THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LVI. SATURDAY, JANUARY 4, 1890. NO 1.

ORIGINAL LECTURES.

CARTWRIGHT LECTURES.

Delivered before the Association of the Alumni of the College of Physicians and Surgeons, New York, November 21, 1889.

BY JOHN S. BILLINGS, M.D.,
U. S. ARMY.

LECTURE III. and IV.

ON VITAL AND MEDICAL STATISTICS.

(Concluded from page 710, Dec. 28, 1889.)

SUPPOSE that, for the sake of testing the relative efficiency of two different modes of treatment, or of the general progress made during a series of years in therapeutics, we take the statistics of a particular disease—which should be one having a tolerably definite train of symptoms, so as to be easily recognized. A disease which is common to select for this purpose is acute lobar pneumonia. Suppose, now, that in a given group of cases of pneumonia, subjected to one method of treatment, the mortality or the proportion of deaths is found to be greater in another series of cases subjected to a different treatment, are we thereby authorized to conclude that that mode of treatment connected with the lowest mortality is really the cause of the low mortality? By no means. Before we can do this, we have to settle the character of the cases, the proportion of those in each group occurring in advanced age or in intemperate persons, or in those affected with other diseases, or in certain races, because all these circumstances influence the death-rate. We have also to take into account the total number of cases in each group, in order to make an allowance for the probable error due to small numbers. If the two groups of cases have occurred in different localities, or have been treated in different institutions, we have then to take into account the special influences of the locality or institution, as far as it is possible to do so, and not until all these corrections have been made can we fairly estimate the relative influence of the treatment.

I have collected the statistics of 209,755 cases of pneumonia occurring in this country and in Europe within the last fifty years, as shown by the following table, giving an average death-rate of 21.11 per cent. The distinction of sex is given in 33,904 of these cases, showing a death-rate of 19.86 per cent. in males and 24.68 per cent. in females:

Pneumonia.	Cases.	Deaths	Percentage of Mortality
Civil hospitals, German and Austrian	44,952	9,868	21.95
Civil hospitals, British	3,467	770	22.20

" " females	11,042	2,726	24.68
	33,904		

The distinction of deaths by ages for each sex is given in 24,557 cases, and from these data I have calculated the proportion of deaths to cases in each age-group, the result showing the immense importance of age as a factor in the death-rate from this disease.

In the absence of statistics of cases and deaths by ages, we can get very little information from statements of death-rates from pneumonia. For example, the death-rate in U. S. hospitals from pneumonia from 1877 to 1888 was 18.72 per cent. of the cases treated. Was this a high or a low death-rate? We can only say that it was probably rather below the average, since the average death-rate for males between 30 and 50 years of age is 19.9 per cent. of cases treated. The importance of such considerations is well illustrated in a paper by Dr. C. W. Townsend and A. Coolidge, contained in THE MEDICAL NEWS, July 27, 1889, p. 85.

This paper is a discussion of all the cases of acute lobar pneumonia treated at the Massachusetts General Hospital from 1822 to the present time, the figures being divided into periods of ten years, making seven decades in all.

The result would indicate a steady rise in fatality from 1822 to the present time. What are the circumstances

which make the cases of pneumonia coming into the hospital during the last few decades more fatal than those which occurred during the first three or four decades? One of the first things investigated was the average ages of the cases of pneumonia admitted in each decade, and the results obtained showed that there was a greater number of patients over fifty years of age in the latter decades, and that the average age is steadily increasing. In like manner, the proportion of cases occurring in persons of intemperate habits, or complicated with other diseases, was examined for each decade. The influence of race was also estimated, with the result that in Americans 9 per cent., in Irish 11 per cent., and in other foreigners 14 per cent. were fatal; that was omitting all fatal cases over fifty years of age who were intemperate or complicated.

Now, if we take the mortality and make the necessary corrections for the influence of age, or proportion of intemperate and complicated cases, and set apart the influence of the causes of death which are entirely independent of treatment, we find that there is but little variation of mortality from decade to decade, and if the influence of race were brought in, we could not infer that, upon the whole, there had been any material change in the mortality of pneumonia for the last sixty-eight years, although there have been very great variations in the treatment during that time.

The conclusions arrived at by the authors are as follows:

1. In the 1000 cases of acute lobar pneumonia treated at the Massachusetts General Hospital, from 1822 to 1889, there was a mortality of 25 per cent.

2. The mortality has gradually increased from 10 per cent. in the first decade to 28 per cent. in the present decade.

3. This increase is deceptive for the following reasons, all of which were shown to be a cause of a large mortality:

(*a*) The average age of the patients has been increasing from the first to the last decade.

(*b*) The relative number of complicated and delicate cases has increased.

(*c*) The relative number of intemperate cases has increased.

(*d*) The relative number of foreigners has increased.

4. These causes are sufficient to explain the entire rise in the mortality.

5. Treatment, which was heroic before 1850, transitional between 1850 and 1860, and expectant and sustaining since 1860, has not, therefore, influenced the mortality rate.

6. Treatment has not influenced the duration of the disease or of its convalescence.

Suppose we try to estimate the relative value of a particular treatment of rheumatism, say by salicylates. We find several tables in medical literature giving the results of treatment by this and other methods. As a type, take the analysis of 1200 cases treated at Guy's Hospital, given by Hood (*British Medical Journal*, December 31, 1881, p. 1119), in which he gives the average duration of illness, number of relapses, and number of cases of cardiac complications, in 350 cases treated with salicylates, and in 350 cases treated without them, and concludes that relapses and cardiac complications were more frequent under the salicylate treatment, but that the pain ceased sooner and the average length of stay in hospital was less. But the cases are not tabulated by sex, age, race, etc., so that we can estimate the bearings of these circumstances on the results; nor in any tables are these results thus classified.

In the fourth volume of the Collective Investigation Record of the British Medical Association there is a table of 655 cases of acute rheumatism, in which the details of each case are given under twenty-seven heads. Dr. Whipham analyzes these, showing how many cases there were in each sex, how many there were in each group of ages, how many in each occupation, etc., but he does not systematically attempt to group these circumstances except as regards teetotalers, temperate and intemperate persons; in other words, he does not tabulate them as a vital statistician would do, so as to show how many of each sex in the first attack in each age-group recovered, died, had sequelæ, etc., when treated by salicylates, and how many when not treated. In attempting to treat the data by formal statistical methods, it will soon be seen that they are totally insufficient in number to give definite results. For example, in temperate males, having their first attack, and treated with salicylic acid, of 25, between five and fifteen years of age, 1 died; of 77, between fifteen and twenty-five, 1 died; of 35, between twenty-five and thirty-five, none died; and of 17, between thirty-five and forty-five, 2 died. Of the intemperate males under the same conditions—16 in all—none died. Are we to conclude that intemperate males with acute rheumatism should be treated with salicylic acid? Not at all—it would require something like 60,000 cases instead of 600 to demonstrate anything of this kind.

Evidently the statistical data which are of the most importance differ for different diseases. If, for example, we are comparing the mortality from pneumonia under different systems of treatment, it is clear that we must have the data with subdivisions by age, and the same would hold good for Bright's disease, and, in fact, for almost all diseases, if the law of decline of vital energy with advancing years holds good. But, for cancer, the data of sex and race are quite as important as those for age.

An important point in medical and vital statistics is to keep the current record, or what may be called the day-book account, entirely separate and distinct from the classification or modes of tabulation. The current record must be made complete at the time, for if any items are left out they can never be replaced. But this record once made may be used in various systems of classification and comparison for many years afterward. If an attempt be made to put this record into the form of a classified return primarily, it is certain to be defective, and will not be applicable to researches of another kind.

In the reviews of the progress of medicine, of which we already have a large supply in the shape of annual addresses and centennial literature, and to which extensive additions will, no doubt, be made at the close of the present century ten years hence, you will find more or less elaborate statements of the advances which have been made in diagnosis, pathology, preventive medicine, and surgical therapeutics in all its branches. Also, it is easy to show that we have made great advances in the

art of relieving pain. But when we seek by statistical methods to determine what advances we have made in the prevention of death by the internal use of drugs, it must be confessed that the data are, for the most part, wanting, and that the optimist and the pessimist can propound theories and beliefs upon nearly an equal footing—that is, that of ignorance of the real facts in the case.

It is easy to see that the statistics of fevers collected in the last century, before typhus, enteric, and relapsing fevers were distinguished from each other, are of little use now, and modern bacteriology has destroyed, to a great extent, the value of the old statistics of tubercular diseases, typhoid fever, cholera, etc., and of the statistics of surgical operations. They have rendered some service in their day, but their value is now chiefly historical. There are, however, in medical literature, a very considerable number ot cases which have been recorded with sufficient detail to be available for statistical treatment which they have not yet received. Death-rates in relation to the number of cases of special forms of disease showing relations of mortality to sex, age, and race are yet to be calculated, and there is material for some good and useful work in this direction.

Within the last twenty-five or fifty years in civilized communities the gross mortality has diminished—there has been a prolongation in the average expectation of life: but how much of this is due to preventive medicine, how much to improved conditions of habitation and to the lowering of the price of food, and how much to improved methods of treatment? Dr. Sweifel endeavored to answer this question in a lecture on the influence of medical knowledge on the life of the people, delivered in Leipzig in 1887 ("Der Einfluss der ärtzlichen Thätigkeit auf die Bevolkerungsbewegung").

Taking as a basis for his calculations the figures of Bavaria for ten years, and those of Saxony for thirteen years, he found that for 100,000 of living population the average number of deaths from tuberculosis increased from 250 to 258, from inflammation of the lungs from 222 to 270, from croup and diphtheria from 98 to 123. He remarks that these are saddening figures; in spite of the sanitarians and health resorts, in spite of ventilation, new methods of treatment by inhalation, compressed air, etc., the number of men who die from diseases of the respiratory organs is steadily increasing, and he queries whether Süssmilch was not right in his phrase "Göttlichen Absterbeordnung"—divine law of death.

On the other hand, he shows that the mortality from typhus has fallen from 62 to 34. But the question is, whether this is due to diminished prevalence of the disease, or to a diminished mortality in the same number of cases of the disease due to the improved medical treatment. It may be noted in this connection that the chief effect of improved sanitation appears in the lessened mortality in children under five years of age, and that it is chiefly in the mortality occurring after these ages that we are to look for the influence of improved medical treatment. In examining this, however, it is to be remembered that improved sanitary conditions affecting chiefly infants, by preserving a number of feeble and sickly children tend to produce a higher rate of mortality in succeeding years. In cases admitting of surgical treatment, and in childbirth, there can be no doubt as to the diminished mortality in the practice of those who use the best accepted modern methods; but these methods are not yet used scientifically by half of the profession, and the results are not perceptible in the general death-rates thus far collected.

It must be admitted that the greater part of the increased expectation of life is probably due to better food, purer water, greater cleanliness, and improved methods of preventing the spread of contagious diseases. If we look at the curves representing the loss of life in large masses of people at different times and places, we see that the laws of life and death have but a narrow range of variation after the age of infancy has passed, and that improvements in therapeutics have lifted the lines but very little. They have lessened suffering greatly, but they have not greatly deferred death.

In our present state of knowledge there are certain forms of disease and derangement of organs whose tendency is to recover without any treatment, or in spite of bad treatment. There are also certain diseases and derangements which are incapable of cure by any known method of treatment. Otherwise, man would not be mortal. Between these two classes is a small number of cases of disease, the result of which depends on the treatment. In order that medical statistics may give us any information in regard to this last class we must have some idea as to the proportion of each of the two other classes.

A very good illustration of some of the ways in which lies can be told with statistics may be found in the various books and papers which have been produced in connection with the anti-vaccination controversy.

In order to understand the relations between vaccination and smallpox, it is necessary to have the death-rates from smallpox given for different periods of life—that is, by age. In this country and in Great Britain we have no data as to the deaths by smallpox by different ages prior to the introduction of vaccination, because the registration of deaths by ages has only been carried on for a little over fifty years. We can, however, for Great Britain, compare the statistics of vaccination for three different periods—the first from 1847 to 1853, in which gratuitous vaccination was provided for the people, but it was purely an optional matter with some whether they should make use of it or not; from 1854 to 1871 vaccination was obligatory by law, but this was mainly theoretical, since the law was practically not enforced; from 1872 to 1880, when the vaccination was rigidly enforced.

Before the introduction of vaccination there were but few persons who did not have the disease at some time in their lives. It appeared in epidemic waves over Europe, usually at intervals of from five to seven years, being about the time required to accumulate, by births, a sufficient amount of susceptible persons to enable an epidemic to make headway. Of course, then, the great majority of persons had the disease in infancy, or in early childhood, and a large proportion of these died. So that in those days the smallpox mortality in the early years of life was high, while those who survived were either protected from future attacks or presented a certain amount of immunity to the poison of the disease, so that the smallpox death-rate of the higher ages was then low. When vaccination came to be general, the young were protected, but were not protected as permanently and completely as would have been effected by an at-

tack of smallpox. The result of this was that the death-rate from smallpox under five years of age fell 80 per cent., while from five to ten years of age it fell 45 per cent., and in the older ages it may even have increased where re-vaccination was not systematically and thoroughly carried out. Taking the English records for 1872 to 1874 and 1877 to 1880, it is found that the proportion of deaths under and over fifteen years of age, per thousand deaths from smallpox, differs according to whether the persons were vaccinated or unvaccinated, as follows: Of 1000 unvaccinated persons dying from smallpox, 672 were under fifteen years of age and 328 over fifteen. Of 1000 vaccinated persons dying from smallpox, 334 were under fifteen and 666 over fifteen, the proportion being, as will be seen, almost precisely reversed under the two conditions.

Whether the data be taken from a State, a large city, or a small town, the results are the same. Take, for example, the records of the town of Kilmarnock, in Scotland. For thirty-six years, from 1728 to 1764, this place had an average population of 4200, and a very accurate register of the births and deaths was kept. During these thirty-six years there were nine epidemics of smallpox, succeeding each other at regular intervals of about four years, just the time required to raise a fresh crop of unprotected victims sufficiently numerous to spread the contagion. Of every 1000 deaths during these thirty-six years, 161 were due to smallpox; in the twenty-six years ending 1879, only 9.9 per 1000 were due to it, or one-sixteenth of the old proportion. In the old days one epidemic left very few unmarked victims for the next one. Those who recovered were pitted for life, and there were very few, except young children, who were unscarred.

By the modern English life-table, of every 1000 children born alive, 2.3 may be expected to die of smallpox before reaching five years of age. In the old of Kilmarnock the proportion was 116 to every 1000.

The statistical mill grinds what is put into it; it enables you to compare the results of different aggregations of circumstances selected by yourself; but it neither guides your selection nor enables you to reason properly on the results. If you compare the death-rate per 1000 of living population in an epidemic of smallpox occurring in a city in the United States in recent times with that of an epidemic occurring in a city in the last century, you will probably find that the death-rate was greater in the modern city than in the ancient one. Perhaps two-thirds of the people in the modern city were properly vaccinated—in the ancient city none were vaccinated. Are we to conclude that partial vaccination increases the death-rate from smallpox? Yes, for a single epidemic year; but if you take a period of twenty years or more for your comparison, you will find the death-rate much lower in the vaccination than in the ante-vaccination period. Why is this? Because in the ante-vaccination period the adults had been through several epidemics of smallpox and had either had the disease and survived, or had proved insusceptible to the virus—being, in either case, protected. The only class of the population in much danger from smallpox in those days were the young children born since the last epidemic, less than ten years ago. But in the modern community, partially protected by vaccination, there has accumulated a considerable number of unprotected adults during the long periods which now elapse without an outbreak, and these increase the fuel for flame, and consequently the death-rate. Comparisons of smallpox statistics for single years are therefore almost worthless.

The results of vaccination may be indicated in another way. At the commencement of its organization in 1761, the Equitable Society for Insurance of Lives, the oldest and most important of life insurance companies, charged 12½ per cent. extra for all persons who had not had the smallpox. In 1781 this was reduced to 11 per cent. extra.

In 1802 it was resolved "that the directors be empowered to grant policies of assurance upon the same terms to persons who aver in their declaration that they have had the cowpox, as to those who aver in their declaration that they have had the smallpox. But if such person shall die afterward of the *smallpox*, then such policy shall be void." In 1823 the words: "But if such person shall die afterward of the smallpox, then such policy shall be void" were stricken out.

In vital statistics, as in other branches of social science, it is not true that the effects of causes acting in combination are equal to the sum of the effects of each of the causes acting separately. Different causes of death having no relation to each other do not have a joint effect which is equal to the sum of the effects of each cause taken separately, and it is, therefore, difficult to bring the phenomena of vital statistics within the boundaries of mathematical formulæ. In the doctrine of this kind of averages time and number are not convertible terms.

Statistics apply to masses of men, to communities, not individuals. We find a mass of matter moving in a certain direction with a certain velocity and endeavor to calculate the direction and amount of the forces which have produced this result. In like manner we may consider the tendency to death in a community as a resultant of several forces and endeavor to estimate the influence of each of these forces in producing the result.

In studying medical and vital statistics one is somewhat in the position of a man on the deck of a large Atlantic steamer, out of sight of land and gazing on the troubled ocean. He sees many waves, large and small, apparently moving in very different directions, and it is not until he has, by careful examination and repeated comparison, learned to distinguish the ripples due to the wind now blowing, the larger cross seas resulting from forces which were acting a few hours before, and the long rolling swells which indicate to some extent the direction and force of the tempest of yesterday, that he can begin to understand the roll of the ship on which he stands; while to appreciate the force and direction of the great current which is sweeping with it all the troubled water and the ship itself, requires skilled observation with special instruments, and the use of charts which embody the experience of hundreds of voyages. So, also, in viewing the records of human life, diseases and death, the variations which are at first most perceptible are often those which are most superficial and which give little or no indication of the magnitude and direction of the movement of the great masses beneath.

The most valuable sources for data relating to vital statistics, and, in many respects, to medical statistics

also, are those contained in the Reports of the Registrar-General of England for the last forty years, and especially in the supplements which have been issued every ten years during that period. Next to these, for matters relating to this country, come the statistics of the State of Massachusetts for the last forty years, the statistics of New Jersey for the last ten years, the Mortality and Vital Statistics of the Tenth Census, and the statistics of Boston, Philadelphia, New York City, and of the District of Columbia. Especially valuable, also, are the vital statistics of Sweden, of Belgium, of Italy as published for the last six or seven years, of Norway, of Switzerland, of Prussia, and of many of the large cities of Western Europe.

The following works will, also, be found useful for reference:

Süssmilch, J. P.: Die Gottliche Ordnung in den veranderungen des menschlichen Geschlechts, aus der Geburt, dem Tode und der Fortpflanzung desselben erweisen. 2 Thiele. Vierte verbesserte Ausgabe, genan durchgesehen und näher berichtiget, von Christian Jacob Baumann. 8vo., Berlin, 1775.

Bertillon, Jacques: Article "Demographie" in Encyclopédie d'Hygiène et de Médecine publique. Paris, 1889, 8vo, tome i. p. 112.

In addition to the Census and registration records, we have another important source of information in vital statistics, namely, the records of life and health insurance companies. These are not as well known to physicians generally as they should be, and I wish, therefore, to call special attention to the two most valuable compilations of them now in existence, namely, the *Insurance Cyclopædia*, commenced by Cornelius Walford, of which five volumes have now been published; and the *System and Tables of Life Insurance based on the Experience of Thirty American Life Offices*, by Levi W. Meesh, published in 1881.

ORIGINAL ARTICLES.

REPORT OF GYNECOLOGICAL WORK, WITH ESPECIAL REFERENCE TO METHODS.[1]

BY R. B. MAURY, M. D.,
OF MEMPHIS, TENN.

THE paper which is here offered presents a brief summary of the more important portion of my operative work during the past year.

In connection with this report some comments are made upon the methods employed, because it is evident that further progress and increased success must depend largely upon the perfection attained in our methods of operating.

With four exceptions all of the operations have been done in a private hospital, built especially for the purpose, and under my own control.

The summary embraces:

21 laparotomies for the removal of ovarian tumors, or of the uterine appendages, or for the relief of obscure disease within the abdomen.

2 laparotomies for ectopic gestation.

28 operations for laceration of the cervix.

14 perineal and vaginal prolapse operations.

5 rectoplasties.

4 anterior colporrhaphies.

The accompanying table presents a synoptical report of the abdominal operations.

Upon many of these cases no comment is necessary; with reference to the others I may properly make some remarks.

It will be observed that out of the twenty-one operations there were two deaths. One of these might be termed accidental; the other was certainly unavoidable.

The one referred to as an accidental death (No. 15) was a case of chronic ovaritis with hyperplasia, and also with extensive cystic degeneration. According to her physician, fearful hemorrhages had repeatedly left her pulseless for many hours. The removal was easy. After the abdominal sutures were introduced some bleeding was discovered, which did not cease upon sponge-packing of the pelvis, or afterward from irrigation with hot water. After examination of the pedicle ligatures, and finding that they were properly tied, a glass drainage-tube was inserted, and the wound closed. A nurse emptied the tube by suction at short intervals.

The patient appearing to be in good condition, I left her for urgent reasons, and on returning in forty-five minutes, I found her pulseless and unconscious.

[1] Read before the Southern Surgical and Gynecological Association, in Nashville, Tenn., Nov. 12, 1883.

LAPAROTOMIES FOR REMOVAL OF OVARIAN TUMORS, DISEASED APPENDAGES, AND FOR OTHER CAUSES.

No	Name.	Age.	Married or single.	Pathological condition or symptoms.	Operation	Adhesions	Drainage.	Hospital or private	Rec. very or death.	Effect of operation.	Remarks.
1	Mrs. L.	53	M.	Papilloma of pelvic peritoneum causing ascites.	Exploration of growth and removal of ascitic fluid.	...	No	H.	R.	Negative.	Returned home and lived one month. The papilloma sprang from the right side of the pelvis; though there were masses on the ovary it did not originate therefrom. Removal was impossible.
2	Miss B.	21	S.	Multilocular ovarian cystoma, weight 40 pounds.	Removal of tumor; remaining ovary healthy.	Yes	No	H.	R.	Complete restoration to health.	Was very feeble and anæmic before operation.
3	Mrs. B.	40	M.	Cancer of small intestine, adherent in Douglas's pouch, causing complete intestinal obstruction.	Exploration and unfolding of intestinal coils.	Yes	No	H.	R.	Clearly to prolong life seven or eight weeks.	History of chronic intestinal obstruction, with acute symptoms of complete obstruction for six days.
4	Miss T.	23	S.	Chronic ovaritis causing complete invalidism.	Removal of uterine appendages	Yes	No	H.	R.	Complete and rapid restoration of flesh and health.	Before the operation she was a mental and physical wreck.
5	Mrs. D.	46	M.	Ovarian monocysts.	Removal of tumor; remaining ovary healthy.	No	No	H.	R	Complete restoration to health.	
6	Mrs. S.	33	M.	Intra-ligamentous cysts with universal adhesions; a very large tumor.	Removal of cyst after 30 minutes work considered impossible; sac cleansed and drained.	Yes	Yes	H.	R.	Ten months after operation is in very fair health; small fistula 2½ inches deep remains; discharge from fistula small	Six months prior to operation had a long fever, supposed to be typhoid. At time of operation was bed ridden, and so feeble that she would have died on the table under a prolonged operation. Intestinal adhesions were extensive and firmly organized.
7	Mrs. P.	41	M.	Chronic ovaritis with strong adhesions.	Removal of appendages.	Yes	No	H.	R.	Was bedridden at time of operation, but two months afterward was greatly improved in health.	
8	Miss M'C	19	S.	Ovarian cystoma of grotesque shape filled with gelatinous fluid which would not flow through trocar.	Removal of tumor; remaining ovary healthy	Yes	Yes	H.	R.	Restoration to health slow but complete.	Patient was anæmic and very feeble; tumor weighed 30 lbs.; from character of its contents and firmly organized adhesions requiring ligatures, long incision was made. She had cough for several months after operation, and recovery was slow.
9	Mrs. C.	27	M.	Fever of hectic type for six months following parturition; tumor in left side of abdomen; symptoms supposed due to abscess.	Abdominal section; no abscess found; tumor was a mass of intestinal coils so firmly united as to be inseparable	Yes	No	H.	R.	Gradual improvement in every respect.	Six months afterward her husband wrote that the only remaining trouble was with the bladder.
10	Mrs. B.	24	M.	Chronic ovaritis.	Removal of appendages.	Yes	No	H.	R.	Restoration to health.	Had long been a confirmed invalid; suffered constant pain, and was bed-ridden.
11	Mrs. N.	25	M.	Cystic degeneration of ovaries, with prolonged hemorrhages.	Removal of appendages.	No	No	H.	R.	Restoration to health.	Ovaries were converted into cysts, and scarcely any stroma was left. The results of operation were brilliant.
12	Mrs. J.	38	M.	Large ovarian cystoma; mostly solid, requiring long incision for removal.	Removal of tumor and of other ovary, which was also much diseased.	Yes	Yes	H.	R.	Restoration to health.	Condition was so bad on admission that temporary relief was attempted by aspiration, but only one cyst could be evacuated, and operation was done next day under unfavorable circumstances.
13	Mrs. R.	36	M.	Thin walled ovarian cystoma of grotesque shape; colloid contents.	Removal of tumor and of other ovary, which was also much diseased.	Yes	Yes	H.	R.	Restoration to health.	Tumor had to be shoved through a long incision; cyst was torn in many places, and colloid contents escaped freely into peritoneum.

No	Name.	Age.	Married or single.	Pathological condition or symptoms.	Operation.	Adhesions.	Drainage.	Hospital or private	Recovery or death.	Effect of operation.	Remarks.
14	Mrs. K.	41	M.	Cystic degeneration of ovaries with severe and prolonged hemorrhages.	Removal of appendages.	No	No	H.	R.	Restoration to health.	Results of operation were brilliant.
15	Mrs. E.	27	M.	Cystic degeneration of ovaries: severe hemorrhages.	Removal of appendages.	No	Yes	H.	D.	Severe hemorrhage, source of which could not be found; death from peritonitis on fourth day.	Abdomen was reopened one hour after operation; patient pulseless and unconscious. Persulphate of iron injected through drainage tube stopped hemorrhage.
16	Mrs. B.	37	M.	Chronic pelvic peritonitis; pelvic organs so matted together they could not be identified.	Removal of right ovary, which was literally dug out.	Yes	No	H.	R.	Complete relief of all the symptoms; too short a time since operation to say more.	After one hour of hard work the right ovary was enucleated from its bed; left tube and ovary could not be identified; normal and painless menstruation three weeks after. Patient went home apparently in perfect health.
17	Mrs. T.	34	M.	Urachal fistula with umbilical hernia; fistula which opened at navel was 7¼ inches deep.	Division of abdominal wall into the fistula as far as pubes; accidental opening of hernial sac.	...	...	H.	R.	Closure of fistula to a great extent; six months afterward a small sinus left which requires washing once in forty-eight hours.	A hernial sac protruded at the navel, and below it on each side of the fistula, in horseshoe shape. This was opened accidentally, first on one side and then on the other, and great care was required to close these openings to prevent the stinking discharge entering the peritoneum.
18	Mrs. L.	42	M.	Pelvic abscess.	Section and drainage of abscess through the abdominal wound.	...	Yes	H.	R.	Abdominal wound healed throughout, full results cannot yet be ascertained since operation was done Oct. 11.	Beneficial results already obtained are, relief from pain caused by abscess in left tube, and removal of obstruction to the rectum, which had almost prevented fecal discharges.
19	Mrs. B.	36	M.	Multilocular thin-walled ovarian cyst with colloid contents and universal adhesions.	Removal of tumor.	Yes	Yes	H.	D.	.....	This was a forlorn hope. Fever for two months; daily vomiting, and bronchitis produced profound anæmia Patient never reacted well, and died twenty-four hours after operation.
20	Mrs. F.	28	M.	Chronic ovaritis with well-marked salpingitis.	Removal of appendages.	Yes	No	H.	R.	Relief of all symptoms on leaving the hospital; and will probably be completely restored to health.	Had been a great sufferer from constant pain; was bedridden and habituated to the use of opium. She had entirely lost her desire for opium before going home.
21	Mrs. H.	41	M.	Chronic ovaritis; ovaries cirrhosed.	Removal of appendages.	No	No	H.	R.	Two weeks after operation had uninterrupted convalescence.	Operation done ten days before the time for a menstrual period. A Graafian follicle had just burst on the surface of left ovary. The tubes were excessively hyperæmic.

LAPAROTOMIES FOR ECTOPIC GESTATION.

No.	Name.	Age.	Married or single	Pathological condition or symptoms.	Operation.	Adhesions.	Drainage.	Hospital or private.	Recovery or death	Effect of operation.	Remarks
1	Mrs. L.	30	M.	Ruptured tubal pregnancy at tenth week.	Removed fœtus and placenta, and tied the tube.	Yes	Yes	P.	D.	Died on third day.	Difficulty of diagnosis, and causes mentioned elsewhere, were the reasons of fatal delay.
2	Mrs. K.	30	M.	Tubal pregnancy at fourth month with extra-peritoneal rupture.	Removed fœtus and drained sac	Yes	Yes	P.	D.	Death from exhaustion.	

The wound was at once reopened, the cavity washed out with hot water, and search again made for the bleeding point, but without success. The drainage-tube was replaced, and the wound again closed.

As the hemorrhage continued, one drachm of liquor ferri tersulphatis was injected through the tube. This at once stopped the bleeding. Reaction with a temperature of 105° F. ensued, and she died on the fourth day from peritonitis. No autopsy was obtained.

I can only speculate in regard to the cause of the hemorrhage; perhaps it was from a torn vein, for the veins in the removed portion of the broad ligament were much dilated.

This case opens the question of the best mode of controlling hemorrhage in a deep cavity like the pelvis, where we cannot see the bleeding point.

I relied on the hemostatic powers of the drainage-tube, but was disappointed. The iron stopped the hemorrhage, but formed a firm plug around the tube, which fixed it firmly in the pelvis. It was removed after forty-eight hours with great difficulty. In a similar case I would be disposed to pack the pelvis around the drainage-tube with iodoform gauze. I have seen Professor Leopold, of Dresden, use gauze alone as a hemostatic, bringing one end out of the lower end of the incision. He removes it in forty-eight hours.

This case, together with Nos. 11 and 14, formed the subject of my paper on the "Clinical History of Cystic Degeneration."[1]

The characteristic features of this form of disease, as illustrated by these cases, are profuse and constant leucorrhœa, persistent intractable metrorrhagia, and ovarian pain. The ovaries were almost complete cysts; the stroma was nearly destroyed; and, though menstruation persisted with great regularity, the microscopist could find no evidences of ovulation in the diseased organs.

As there was no tubal disease, and presumably from the subsequent history of Cases 11 and 14, no disease of the endometrium, the conclusion was unavoidable that the severe hemorrhages were the result of cystic degeneration.

The case referred to as one of unavoidable death was No. 19. This was a multilocular, thin-walled ovarian cyst, with colloid contents, and universal adhesions, in an anæmic woman, who was sent to me in desperate circumstances, after all attempts to rally her had failed. She was exhausted by a fever of two months' continuance; by daily vomiting and inability to take food; and, lastly, by an attack of bronchitis, which resulted from exposure at night while waiting four hours for a delayed train.

The operation was done after the bronchitis was relieved. The cysts which formed the tumor were numerous and small; the walls were fragile, and tore when caught by the forceps; the contents would not flow through the large trocar, and a portion escaped into the abdomen. The adhesions were universal and strong. On the posterior surface of the tumor the small intestine was extensively attached, and upon eight inches of its length it was necessary to leave the outer layer of the cyst wall. The pedicle was tied early in the operation, and subsequently the upper portion of the cyst was removed. This was necessary to get at the intestinal adhesions.

After an hour's work I had the satisfaction of closing a dry and clean peritoneum—but the shock was too great for so feeble a patient. She never fully reacted, and died the next day.

In Case 3 the operation was done for relief of acute symptoms which supervened in the course of chronic intestinal obstruction. For six days neither flatus nor feces had passed. There were pain and constant vomiting. A small nodulated tumor was felt behind the uterus. This was supposed to be a cancerous ovary.

On making the section, it was found that the uterus, ovaries, and tubes were healthy. The tumor was a cancerous growth involving a coil of small intestine and fixing it firmly in Douglas's pouch. Cancerous nodules were found in its mesentery, upon the adjacent omentum, and on the neighboring intestinal coils.

After untwisting the coils and separating a few adhesions, the wound was closed with the expectation that the patient would die in a day or two. But during the night the vomiting ceased, and the next day she began to take food. On the third day there was a natural fecal evacuation, which was repeated at intervals of three or four days.

She went home on the fifteenth day, and lived one month.

Nos. 16 and 18 may be classed among the most difficult of pelvic operations. In the former, after an hour's work the right ovary was dug out of its bed of old adhesions. The vermiform appendix was firmly fixed close to it, but the Fallopian tube could not be made out. On the left side, neither tube nor ovary could be discovered, the tissues being fused together and contracted by inflammation.

In the latter case there had been a history of disease for fourteen years, following parturition. For eight or nine years she had been a great sufferer from pain in the left hip, associated with an exudation fixing the womb in a position of retro-version.

In September she came under my care with a tumor in the left hypogastric region. The pelvic exudation, felt through the vagina, was of stony hardness: a firm ring was formed around the

[1] Transactions of American Gynecological Society, 1889.

rectum which prevented the passage of the index finger, and seriously obstructed defecation.

On making the section, the abdominal wall was found nearly three inches thick, and on the left side very unyielding and resistant from inflammatory thickening of the peritoneum. The omentum was adherent to the pelvic brim, and strong adhesions were broken before the tumor was reached.

After a determined effort of three-quarters of an hour, the tumor was, to a great extent, separated from its posterior attachments, but a cartilaginous button remained, connecting it with the rectum. I could do nothing toward separating the anterior attachments of the tumor. If this had been possible, I would have separated the rectal attachment with scissors, and controlled hemorrhage by the pedicle ligature.

Under these circumstances the sac was aspirated, and nearly two ounces of pus removed. The opening was then enlarged, and the sac and pelvis thoroughly irrigated by means of the siphon-trocar. Two drainage tubes were then inserted, one into the pus sac, the other into the pelvis. The pus sac could not be attached to the abdominal incision. Both drainage-tube openings were closed by the end of the second week.

This method of drainage I had made use of in a previous case under similar circumstances with satisfactory results.

Much uncertainty, however, surrounds the future of both these cases, as it does that of all incomplete operations.

The methods which I have followed with scrupulous care are those which have been developed by the labors of Sir Spencer Wells and his able successors in the Samaritan Hospital, and by Dr. Keith, who worked contemporaneously with him; and, lastly, by Mr. Lawson Tait, who may be said to have well-nigh solved all the problems involved in the successful treatment of inflammatory disease of the uterine appendages, and in the management of ectopic gestation.

These methods may be summarized as follows:

1. An aseptic field of operation, and an aseptic surgeon.

2. A small incision—in the case of inflammatory disease in the pelvis, just large enough to introduce, and work with, two fingers.

3. Aseptic silk ligatures, as fine as is consistent with safety in tying.

4. Enucleation of diseased structures, in spite of firm adhesions or even profuse hemorrhage.

5. Irrigation by means of the siphon-trocar as a substitute in most cases for sponging; using simple hot water for this purpose, and excluding all antiseptics.

6. Drainage often, and whenever one is in doubt as to its necessity.

7. Careful replacement, by spreading out, of the omentum, before proceeding to close the wound.

8. Inclusion of all the structures in passing the abdominal wall sutures; and placing the deep sutures one-half an inch apart.

9. The use of means for moving the bowels on the second or third day, after removing the appendages; and the avoidance, if possible, of opium.

Out of forty-three patients surviving abdominal operations from a few months to several years, I know of but one who has a hernia. This was the result of leaving off her bandage during an attack of dysentery, which occurred two months after a section one inch and a half in length, for an intra-peritoneal hæmatocele.

My cases have all been in private practice. I have heard from most of them repeatedly after operation, and I think if hernia had occurred I would know it.

I have had one tube-sinus which still continues to discharge at times, although one of the pedicle-ligatures was cast out sixteen months after the operation.

I will now consider the cases of ectopic gestation.

The first case was under the care of Dr. W. W. Taylor, who, suspecting ectopic gestation, requested me to see her with him on Feb. 17th. Her history is as follows:

Jewess, aged thirty years, of stout build, who had one child seven years ago. No conception since.

Her health was good and menstruation normal to Dec. 20, 1888, when the menstrual period continued five days.

Six weeks later a slight bloody discharge appeared, accompanied by pain in the hypogastrium and right iliac region. The pain was not continuous: the bloody discharge was a mere stain.

She suffered from nausea, and thought she was pregnant.

An examination showed the uterus to be somewhat enlarged, but in its normal position. Its mobility was impaired and there was decided peri-uterine tenderness, but no pelvic tumor could be found. The pulse was 100; temperature 99½°. The patient did not appear to be very ill, and the symptoms, I thought, rather pointed to a normal pregnancy, with slight pelvic peritonitis.

Until the end of the first week in March there was little change; the symptoms were rather better.

There was a continuous bloody discharge, but the pain was less, and at longer intervals.

No membrane or shreds had been, or were subsequently passed.

On March 8th she was suddenly seized, while at stool, with severe pain. Dr. Taylor found her pale, with cool extremities, and feeble pulse.

A hypodermatic of morphine and other means readily brought about reaction.

On the following day we again examined her, and found the uterus fixed, but pushed to the left side by a tumor which occupied Douglas's pouch and the

right side of the pelvis. The diagnosis was now reasonably clear.

I pause in the recital of this history to remark that, at this time, an abdominal section should have been made; but how prone are we to lay to our souls the flattering unction which Schröder thus expressed: "With care, fatal issue is as a rule avoided: the subjects recover with unexpected quickness: the numerous lymphatics of the pelvis quickly absorb the blood."

Dr. Taylor's report says, "Symptoms of mild peritonitis continued; her condition improved; no opium was required, and she was free from pain for a week. Her appetite was better, and all the symptoms favorable. The tumor did not increase in size."

On March 27th she was seized with severe pain: the pulse jumped from 104 to 130, and there was increased peritonitis.

The situation had already been fully explained to the husband; preparations had been fully made for an abdominal section, and this was at once urged. Notwithstanding his foreknowledge, her husband did not give his consent to the operation until March 30th.

The patient's condition was then very unfavorable: the abdomen was swollen, the skin had assumed a deep icteroid hue, and the pulse was very feeble. The abdomen was opened with the assistance of Drs. Taylor and R. W. Mitchell.

A large amount of clots and dark, bloody serum was found, with a ruptured Fallopian pregnancy of about the tenth week, the fœtus being discovered alongside the right tube.

After removal of all these and ligation of the tube, the abdomen was irrigated with hot water and a drainage tube inserted.

Though she bore the operation well, and was put to bed with a pulse of 104, the patient did not improve.

There was much discharge of dark fluid from the tube; the color of the skin deepened; the pulse increased in frequency; she became delirous, and died on the third day.

Case II.—Mrs. K., aged thirty years. Had one child eight years ago. No conception since.

Her health was good and menstruation regular up to the 15th of May, 1889. About the middle of June there was a slight "show." Soon after this she began to have nausea, and concluded that she was pregnant.

On the night of July 19th there was a discharge of blood lasting for several hours, and unattended with pain.

On August 12th, and several times afterward, there was a slight bloody discharge.

About the last of July symptoms of peritonitis appeared; the abdomen swelled, was tympanitic and very tender on pressure. Pain was also complained of, oftentimes severe enough to require morphine. There was a slight rise of temperature and pulse.

The vomiting which began after the 15th June continued. On the 15th of September, when first seen, she was emaciated and feeble from inability to take food and from long suffering. She was confined to bed, and required an opiate nearly every day. The pulse was 90; temperature 99°. The entire abdomen was swollen, very tender to the touch, and tympanitic except over the lower portion, where an ovoid tumor was observed rising from the pelvis as high as the navel, and lying chiefly to the right of the median line. The tumor was dull on percussion, and no fluctuation was perceptible.

A vaginal examination showed that the uterus was pushed to the left side, its fundus lying forward, and the cervix directed toward the left sacro-iliac symphysis. It was fixed in this position by a tumor which occupied the middle and right side of the pelvis, which was evidently a part of the uterus and also of the abdominal swelling. The uterine sound entered three and one-fourth inches. Its withdrawal was followed by a bloody discharge. The cervix was swollen, soft and patulous, and all the tissues were unusually succulent. The purple hue of the vagina so often present in pregnancy was absent, and no mammary signs of pregnancy were detected.

I at once made the diagnosis of a four months' tubal pregnancy, with rupture between the layers of the broad ligament.

It was evident to me, and to Dr. Edward Mitchell, who saw her with me, that the patient could not live to the end of the nine months. Her only chance was in immediate operation, and the gravity of the case was at once explained to her husband.

With a view of diminishing the vascularity of the sac, and thereby lessening the dangers of laparotomy, I proposed to destroy the fœtus by electricity, and remove it after a week or two. A Gaiffe battery was used the next day, and again on the day after. Strong uterine pains followed this treatment, and a complete decidual mass as thick as the index finger was expelled. The battery was not used again, and as it was evident that the patient was losing ground, laparotomy was done on September 20th.

On opening the abdomen a dark tumor appeared, with uneven surface. It filled the pelvis, and rose to the umbilicus.

Very nearly in the line of the incision was an ovoidal prominence which did not fluctuate. Believing it to be the fœtal sac, I passed a very small trocar in to remove the fluid, but nothing escaped through the canula. After moving the canula in several directions, a bloody stream issued from it. On withdrawing the canula the delicate sac ruptured to the extent of allowing the extrusion of a four months' male fœtus.

There was quite a free flow of blood from the sac, but it was promptly stopped by packing with iodoform gauze.

The edges of the sac were then stitched to the abdominal incision. I was desirous of avoiding drainage in this case, and of leaving the placenta, as Mr. Tait has recommended, by filling the sac with water and afterward closing it so as to exclude the air; but the accidental injury to its wall causing

bleeding, made it necessary to drain, and the gauze was relied on for this purpose.

After this operation the abdomen, much distended, was not appreciably diminished in size, and the upper sutures were tied with considerable tension.

The patient's condition was not improved: she was much exhausted, and was restless. The next day her pulse was 96, and temperature 99°. There was much watery discharge from the sac. Hiccup became a troublesome symptom. On the third day the stomach was quiet, and temperature normal, but the pulse had risen to 115. On the evening of the fourth day she died, apparently from exhaustion.

Autopsy: The edges of the sac were firmly adherent to the abdominal wall. The placenta was attached to the left wall of the sac. The large tumor rising to the umbilicus was found to be almost entirely a hæmatoma, between the layers of the right broad ligament, which had detached the peritoneum from the right and posterior walls of the pelvis, and partially from the posterior surface of the uterus.

The tumor was composed of large masses of fibrin, much black coagulum, and a good deal of fluid blood.

Could such a mass be disposed of except by suppuration? The mass after removal, draining of liquid, and exclusion of coagula, was larger than a child's head.

Could it have been enucleated and tied off? The hemorrhage and shock would probably have destroyed the patient on the table.

The peritoneum was clean. There were no adhesions, but the intestines were distended as before the operation.

The fœtal sac occupied an insignificant part of the tumor. The fœtus had been dead a few days only.

I have previously reported two cases of ectopic gestation in my own practice, one of which ruptured at eight weeks, and recovered without operation. The second was operated on six months after completion of the natural term of pregnancy. The latter patient was far advanced in phthisis, and the operation was done at her request. She recovered from the operation, but died a month later from lung disease—both apices showing cavities at the autopsy. This autopsy demonstrated beyond all doubt that the fœtal sac was entirely extra-peritoneal; that the gestation had originated in the right Fallopian tube, and had developed between the layers of the broad ligament, downward to the pelvic floor, laterally to the pelvic wall, and upward into the abdomen.

The case is of unusual interest, because, next to Berry Hart's celebrated frozen section, it was the first published to demonstrate an extra-peritoneal abdominal gestation. With this experience, and after much thought and study of the subject, I have but little confidence in my own ability to diagnose ectopic gestation in the early months, before the period of rupture.

Of the twenty-eight operations for the repair of lacerated cervix, all were successful, and in no case was there fever or other complication. In one case I availed myself of a suggestion made by Dr. Bache Emmet—to operate first on but one side, and several weeks later, when involution has proceeded somewhat, to close the rent in the other.

Emmet and Schatz, on the same day of the month, and in the same year, 1883, the one in Philadelphia, the other in Freiburg, read papers before societies on injury to the pelvic floor in childbirth.

Each pointed out how displacements of the pelvic viscera, and especially prolapse, were dependent much more on such injuries than upon a laceration of the perineum. One regarded the injury as an overstretching and separation from the attachments of the pelvic fascia. The other considered it to be a laceration of the fibres of the levator ani, close to their insertion into the descending ramus of the pubes.

Subsequently Hadra, as a result of his careful and intelligent study of the subject, was satisfied that there was a true diastasis, near their sacral attachments, of the levators, and a retirement of the muscular strata toward the pubic insertion.

While this anatomical discrepancy of opinion still exists, and we are yet in ignorance of the exact nature of the injury, a decided modification of our methods has resulted, and the operations which I have been doing since Emmet's paper was published have had for their object a restoration of the support which is afforded by the pelvic floor rather than a simple restoration of the perineum proper.

In most of my cases the operation performed has been that which Emmet has described for "Prolapse of the Posterior Wall of the Vagina," and the results which I have obtained by this method have been eminently satisfactory.

In a few cases during the past year I have done Martin's operation, which is particularly appropriate when there is great relaxation of the vagina.

I may here remark that Martin's operation consists really of two operations, the first being a double elytrorrhaphy, the denudations being on each side of the columna rugarum posterior, while the second has for its object the building up of the perineum. In the second the denudation is almost identical with that of Emmet, while the suturing of one is quite different from that of the other.

In my table of operations there are five recto-plasties and four anterior colporrhaphies. These have been done according to Martin's method. This method is so simple and possesses so many merits that I can strongly commend it. It would be improper in this place to go into details which

have been published elsewhere (*American Journal of Obstetrics*, October, 1887), but I may say that the peculiar features of the method are the following:

The denudation, whether it be on the posterior or anterior wall, is done with the knife, the mucous and connective tissue layers being removed so as to expose the wall of unstriped muscular fibre.

A single continuous suture of catgut closes the wound, beginning at its upper angle, working downward, and, if it be on the posterior wall, including the rent in the rectum, and finally, closing the perineum.

Suturing in layers relieves tension, brings about union over a large extent of raw surface, and avoids the formation of pockets.

The method is to be commended for its extreme simplicity, the rapidity with which it can be done, the great comfort to the patient afterward, and because there are no sutures to be removed. One requirement for its successful performance, I am sure, is good catgut.

Without intending to make invidious comparisons, I may say that the raw catgut which Martin himself prepares, Nos. 2 and 3, known by the trademark "Wiesener," and made by Paul Hartman, of Heidenheim, and to be easily and very cheaply bought in any of the German cities, comes very near to perfection as a ligature.

This catgut I have prepared by Martin's formula, immersing it for six hours in a sublimate solution, 1 to 1000, then removing and drying it with a towel, and, lastly, immersing it in a mixture of oil of juniper and alcohol, one to two.

After a week's immersion it is ready for use, and is then a perfect ligature—as flexible as silk, exceedingly tough, and does not disappear from the tissues under seven days.

Of the five rectoplasties, all united most satisfactorily, and were complete successes. There was perfect retention of feces and gases. In but one of the cases was there cause for anxiety. In this the operation was done to close a large recto-vaginal fistula of eighteen years' standing, in a woman who was several years past the menopause, and whose general health was completely wrecked from long residence in a tropical climate, and from incessant headaches, which required the use of opium.

Through the fistula a large hemorrhoid frequently protruded in a half-strangulated condition; therefore, an operation for hemorrhoids was first required. Subsequently the recto-vaginal septum was divided to the fistula, the upper margin of which was one and one-half inches from the anus. The edges of the fistula were pared, and the lateral folds of the vagina denuded. The entire wound surface was then closed by the continuous catgut suture in tiers. A small fistula remained, but three months later the patient came to show me that a complete success had been accomplished, the minute opening having closed. The extreme thinness of the septum, and the abundance of cicatricial tissue near the fistula, made a successful result very improbable. In this operation of Martin for complete rupture of the perineum into the rectum, as in that of Bantock and others, no attempt is made to recover and suture the ends of the ruptured sphinter.

Emmet thinks that freshening the edges of the muscle, and bringing them into perfect apposition, are necessary.

It is difficult to prove that the atrophied fibres of the sphincter in an old laceration are ever recovered, and if they were, the union of the ends would not be muscular, but only by connective tissue. While discussing the repair of muscle in wounds, Mr. Thomas Bryant states that his observations "confirm those of Billroth, who declares that he has never seen anything which he could regard as a reformation of muscular fibres, and that the cicatrix in muscle is almost entirely connective tissue, the extremities of the muscular fibres after division and repair uniting with the cicatricial tissue in the same way as they do with the tendons." (*Internat. Cycloped. of Surgery*, vol. ii.)

The four anterior colporrhaphies were for very extensive prolapse, and in each the denudation extended from the meatus urinarius to the cervix uteri. They were satisfactory in every respect.

During all the plastic operations herein discussed the field was irrigated by a gentle stream of pure warm water, and the wound thereby made aseptic.

After operation the only need for opium is to control the bowels, which in the rectoplasties are not allowed to move until the fifth day. Subsequently they are moved every two or three days.

No vaginal douches are used; merely irrigation of the external genitals after urination.

The rectal tube is of immense value after rectoplastic operations.

In the work herein submitted, I may state that there has been nothing like sepsis in a single case.

Note.—In rectoplasties, fearing a possible solution and giving way of the catgut before union is obtained, I have as a precaution passed a special suture of silkworm-gut at the anal margin through the ends of the sphincter. I think the benefit from the suture, to which Emmet attaches so much importance, is not in procuring union of the sphincter, but in holding the ends of the sphincter quiet, and thus preventing their contractions from interfering with union.

A French Hospital in Turkey.—The *Press and Circular* states that a hospital and dispensary will be established at Constantinople at a cost of about $800,000, the appropriation to be chiefly obtained from legacies.

ASTHMA AS A NEUROSIS.

BY J. G. CARPENTER, M.D.,
OF STANDFORD, KY.

"ASTHMA is an affection characterized by severe paroxysmal dyspnœa, recurring at more or less marked intervals, generally in the night, the dyspnœa being due to spasmodic contractions of the bronchi, produced by a variety of causes."—*Quain's Dictionary of Medicine.*

"Asthma may be defined as dyspnœa of a peculiar urgency and violence, generally paroxysmal and recurrent; often periodic; not necessarily attended by cough or expectoration; accompanied usually by dry râles, and compatible with easy and healthful respiration in the intervals of the attacks."—*Reynolds's System of Medicine.*

"A violent form of paroxysmal dyspnœa, not dependent upon structural lesion; with great prolongation of the respiration, and with absence of all symptoms of the disease during the intervals between the attacks. Its synonyms are *asthma convulsionum* (Willis); *spasmus bronchialis* (Romberg, *asthma nervosum* or *Krampf der Bronchien*)."—*Pepper's System of Medicine,* Beimer.

A most zealous advocate of the spasm theory of asthma as a neurosis depending upon tonic spasm of the bronchial muscles, and caused by faulty innervation of the pneumogastric nerve, "claims that this theory is confirmed by clinical experience; and that the suddenness with which the attack comes on and disappears, the long and forced respiration, with the sibilant râles, and other evidences of stenosis which accompany it, admit of no other explanation." As a proof of this, spraying the rhino-pharyngo-laryngeal chambers with cocaine, the internal free use of chloral or the hypodermic injection of morphine, or the latter with atropine, inhalation of ether or chloroform, or the relaxing effect of ipecac, antimony, or apomorphia, by nauseation, causes the immediate disappearance of the paroxysm and the concomitant symptoms. The absence of morbid anatomy to indicate the specificity of asthma, the suddenness of its coming and going, the intervals of repose, the enjoyment of perfect health at these periods, explain its neurotic origin.

Lebert considers that bronchial spasm is an all-important factor, but denies that it is in itself sufficient to account for the sudden and enormous inflation of the lungs observed in this disease. He doubts the possibility of a valvular closure of the bronchi, but believes that the bronchial spasm, which he regards as primary, causes secondary contraction of the diaphragm and inspiratory muscles of the neck and chest.

Theodore Weber discards the above theories because neither bronchial spasm nor contraction of the diaphragm explains why catarrhal secretion should appear at the close of an attack in which at the commencement there was no catarrh. He attributes the phenomena of asthma to sudden swelling of the bronchial mucous membrane, the result of dilatation of the bloodvessels, produced through the agency of the vaso-motor nerves, thus reviving the fluxionary theory of Traube.

To prove this theory Van Loven's experiments are cited, which prove that irritation of the sensory nerves is followed by the reflex engorgement of the territory to which they are distributed.

Weber considers that this engorgement of the bronchial mucous membrane is somewhat similar to the acute swelling and stoppage of the nostrils to which many persons are subjected—a closure which does not last longer than a few moments, and which is attended with increased redness and swelling of the Schneiderian membrane. The mucous membrane of the nostril and that of the bronchi being both parts of the respiratory tract and somewhat similar in structure, he concludes that the process in the nostril is analogous to that which occurs in the bronchi during the asthmatic paroxysm. He cites the fact that such occlusion of the nostril is often the precursor of the asthmatic attack, and in some cases continues throughout.

Max Schaeffer maintains that asthma is due to bronchial fluxion as advocated by Weber, but claims that hyperæmia is followed by spasm of bronchial muscles, the former being primary, the latter secondary. Reid, with the most recent writers, believes that asthmatic attacks are due to pathological conditions in and about the upper air passages, such as naso-pharyngeal and laryngo-tracheal catarrh, polypi, hypertrophies of turbinated processes, tonsils, both facial and pharyngeal, or one or both, and enlarged cervical glands. The writer believes that deviated septa, nasal occlusions, diseases of the antrum, maxillæ, decayed teeth, and impacted cerumen in the auditory canal, all act as irritants, and, the irritation being transmitted through adjacent nerves to the organs involved, causes bronchial spasm.

Pathological Anatomy.—Bronchial asthma is purely a neurosis. No ante- or post-mortem anatomical lesions are found to indicate a condition peculiar to asthma. The most that can be said (pathologically) is that there are certain functional disturbances which disappear with as much certainty and rapidity as they appear, and that asthma is, as a rule, but the sequel of some lesion in the upper respiratory tract as a predisposing cause, followed by an acute or sub-acute catarrh of the upper air-passages as an exciting cause—either a rhinitis, rhino-pharyngitis, ethmoiditis, sphenoiditis, or frontal inflammation.

There may be present only the dry or congestive stage of acute catarrh, the liquefactive or the muco-purulent stage, or there may be irritation of the

mucous membrane and nerves supplying it, of the upper respiratory tract. The quieting of this irritation, the arrest of the acute catarrh in one or more of its stages, checks and cures the asthma temporarily. The cure of any chronic catarrh of the upper air-passages, removal of myxomata, fibromata, turbinated hypertrophies, nasal occlusions—as enchondromata, exostoses, spurs and ridges on the septum, deviations of the septum, diseases of the antrum, and decayed teeth—prevent the return of the disease.

In some cases irritation from tumors in the abdominal cavity, hepatic or gastro-intestinal irritation may be transferred to the pneumogastric nerve, and cause bronchial spasm. In cases of long standing, owing to often-repeated attacks of asthma, the air-cells may become permanently distended, attenuated and ruptured; emphysema may result, or the pathological lesions of chronic bronchial catarrh and its accompaniments in the upper respiratory tract may be found on making a post-mortem examination.

Hyper-distention of the alveoli and impaired circulation of the blood by repeated attacks of asthma will also produce cardiac disease.

The dyspnœa of bronchitis, cardiac disease, emphysema, spasm of the glottis, œdema of the glottis, tracheal stenosis, spasm of the diaphragm, paralysis of the posterior crico-arytenoid muscles, and embolism of one of the middle or larger pulmonary arteries, should not be mistaken for asthma. The asthma attending hay-fever will not be discussed in this paper, further than to state that the predisposing etiological factors which cause asthma have also been found in hay-fever, viz., diseases located in the upper respiratory tract, and that the medical, surgical, hygienic, and climatological factors which relieve and cure asthma have also cured this troublesome malady.

Rheumatism and gout play an important *rôle* in asthma, and during sudden changes of weather or temperature, asthma, bronchitis, or some skin eruption, may appear in the absence of a rheumatic or gouty attack. Uræmia, from diseases of the kidneys, may cause the most severe attacks of asthma.

The most constant change observed in the bronchial tubes in old cases of asthma is hypertrophy of their muscular fibres, causing thickening of their walls and diminished calibre. In other cases they are dilated, but this condition is due rather to the concomitant bronchial catarrh than to the asthma. The venous blood, obstructed in its course through the lungs, accumulates in the pulmonary artery, and, pressing back upon the right ventricle, excites it to increased action, which, in the course of time, leads to hypertrophy of its muscular fibres and dilatation of its cavity. Syphilis, lead and mercurial poisoning, may cause asthmatic attacks through irritation of the medulla oblongata or through the pneumogastric nerve, in the same manner as does rheumatism, gout, uræmia, or malaria.

Malarial asthma, while not so common as malarial neuralgia, does often exist, and is relieved and cured by anti-malarial treatment.

Some of the most distressing cases of asthma the writer ever witnessed were due to a retroversion of the uterus and pressure on the sacral nerves. The treatment in these cases consisted in the use of large hypodermic injections of morphine and atropine to allay the paroxysms, while further attacks were prevented by replacement of the womb and the adjustment of a suitable pessary.

Various authors claim that asthma is inherited and even give examples where the father and three of four children had asthma, and where the disease appeared in four generations; or one generation may have had asthma; the next, gout or rheumatism; the third, epilepsy; and the fourth, asthma.

The writer of this paper doubts the heredity of asthma, but believes that a neurotic diathesis is inherited, and that from certain predisposing and exciting causes asthma would be caused in one case, epilepsy in another, and St. Vitus's dance in a third.

Riegl states that the action of the irritant in asthma may be explained in one of three ways: (1) Both the spasm and congestion may be the common result of the irritant; (2) the catarrh may cause the spasm; or (3) the spasm may, secondarily, cause the catarrh.

Most cases of asthma occur in childhood: from one to ten years, 71 cases; ten to twenty years, 30 cases; twenty to thirty years, 39 cases; thirty to forty years, 44 cases; forty to fifty years, 24 cases; fifty to sixty years, 12 cases. (Salter.)

The reason that asthma is so much more prevalent in childhood is, to the author's mind, due to the improper management of the child at birth; even in half an hour after its advent, a rhinitis is developed from undue exposure and the rapid evaporation from the body and radiation of heat: the child starts in life with a cold, has continual recurrences, thereby establishing chronic or subacute catarrhal inflammation of the upper air-passages, which with its sequelæ furnishes the most potent predisposition to asthma. The prognosis is good if the proper treatment is given before irreparable structural lesions have taken place. The patient starts wrong, and goes wrong until he falls into the hands of the rhinologist, and, as a rule, in due time is cured, for as asthma is a neurosis, the removal of the cause removes the effect.

Children and adolescents recover with proper treatment more rapidly than adults.

Persons of rheumatic, gouty, or phthisical diathesis do not recover so rapidly.

Dr. F. H. Bosworth (*The American Journal of the Medical Sciences*, September, 1888) reports an analysis of eighty cases of asthma, with special reference to local diseases of the upper air-tract, and concludes that asthma is a reflex disease. He divides asthma into hay-asthma and perennial asthma, the former being a vaso-motor rhinitis, the latter a vaso-motor bronchitis, and believes that they are virtually one and the same disease, the paroxysms being excited by atmospheric conditions.

Hay-fever depends on three conditions: 1. A neurotic habit, as shown by Beard. 2. The presence of pollen. 3. A disordered condition of nasal passages.

Asthma depends on three conditions: 1. Neurotic habit, as shown by Salter. 2. Disease of nasal mucous membrane. 3. Obscure conditions of the atmosphere.

According to Bosworth, a large majority, if not all, cases of asthma are dependent upon some obstructive lesion in the nasal cavity. This is proved by the relief furnished by local application of cocaine, and by the permanent relief of so many cases by removal of the obstruction in the upper air-passages. Thirty-four of Dr. Bosworth's 80 cases of asthma had hay-asthma; 46 had perennial asthma; 29 of the cases of hay-asthma and 33 of perennial asthma had nasal symptoms preceding the attack; 60 of the cases were ushered in by sneezing and other nasal symptoms; 84 gave a history of catarrhal trouble. Of the 34 cases of hay-asthma, when examined as to local condition in the nose, 9 had hypertrophic rhinitis, 12 had hypertrophic rhinitis and deflected septum, 4 polypi, 5 polypi and deflected septum, 3 deflected septum, and 1 had elongated uvula.

Of the 46 cases of perennial asthma, 13 had hypertrophic rhinitis, 11 nasal polypi, 11 hypertrophic rhinitis and deflected septum, 6 polypi and deflected septum, 2 adenitis and hypertrophic rhinitis; thus showing that all of the 80 cases of asthma examined as to the condition of the nose presented some obstructive lesion. The treatment in these 80 cases was the use of caustic, the nasal saw, and the snare. In the hay-asthma cases 18 were cured, 14 improved, 1 unimproved, 1 result unknown. In the cases of perennial asthma 28 were cured, 12 improved, 2 unimproved, and 4 unknown.

The writer has had under observation between 20 and 30 cases of asthma, and can confirm the tabulated analysis of Dr. Bosworth. In fact, the above statements are the uniform experience and observation of all practical rhinologists.

The statistics of Salter show that persons from one to ten years of age are subject to asthma. This, no doubt, is due to the facts that in addition to the improper and unhygienic treatment given the infant at its birth, producing a chronic or subacute rhinitis, scarlatina, measles, whooping-cough, diphtheria, and roseola, bring about the most favorable predisposing causes of asthma, viz., diseases of the upper air-tract. Beside the conditions just enumerated may be mentioned improper dress, the follies of fashion, the use of tobacco, alcoholic beverages, snuff, and certain occupations—such as milling, cigar-making, blacksmithing and hemp-breaking.

A lady, aged twenty-six years, mother of two children, eight weeks after her second confinement consulted the writer. She had chronic naso-pharyngitis, subinvolution of the uterus, anal fissures, and spasm of the sphincter ani, and had been subject of late to asthmatic attacks. Divulsion of the sphincter ani, the curing of the subinvolution of the uterus and the catarrhal inflammation of the upper air-passages prevented a return of the asthma, proving conclusively that in this case the asthma was a neurosis. There was no permanent relief until after divulsion.

One of the most distressing forms of asthma is uræmic asthma. In the treatment of this variety, there are three indications: 1. To eliminate from the system the poison already present. 2. To prevent its deleterious effect upon the nerve centres and terminal nerves. 3. To prevent the further or excessive formation of urea. The first is done by the hot air bath, hot water and steam bath, or pilocarpine causing copious diaphoresis, by digitalis and acetate of potash, frequent draughts of hot water, and washing out the kidneys and urinary tract by free diuresis. Also by the elimination of waste products by hydragogue cathartics. The second indication is met by the effects of morphine on the terminal nerves and on the nerve centres. The third indication is to circumscribe the diet, feeding the patient on milk, and preventing the formation and absorption of further poisons. Dr. Stephen Mackenzie in the London *Lancet*, states: "I think all the facts of uræmic dyspnœa, its periodicity, sudden onset, and relief by anti-spasmodics, point to a spasmodic neurosis due to poisoning of the nerve centres, and suggests that the spasm is rather of the bloodvessels than of the bronchial tubes. Beside the hypodermic use of morphine in renal asthma, the author has seen the happiest results in cases of uræmic convulsions and coma. The following case is an example of this:

Patient, a female about twenty years of age, had been comatose twelve hours or more, and had had from one to three convulsions every hour. The case had been diagnosed "hysterical coma and convulsions." One-fourth grain of morphine was given hypodermically, and the convulsions lessened; in two hours another fourth of a grain was given, and in an hour the convulsions had ceased. In two hours from the administration of the last dose, another was given. An hour afterward patient was partially conscious, and in three hours was entirely

conscious, thoroughly herself and talked freely. The pupils had contracted to the normal size, pulse was full, strong and regular, respiration and temperature normal. With every dose of morphine thirty drops of tincture of digitalis were given.

To Professor Loomis, of the Medical Department of the University of the City of New York, the profession is indebted for the use of morphine as an antidote to uræmic poison. He states that when premonitory symptoms of acute uræmia were found, as well as during the active manifestation of uræmic intoxication, so far as he is able to judge, its administration has been uniformly followed by good results. In no instance is he aware that he has caused a fatal narcotism. Dr. Loomis has given from one-half to one grain injections to a patient in complete coma. He claims positive relief of distressing and dangerous symptoms and in addition: (1) to arrest muscular spasm by counteracting the effects of the uræmic poison on the nerve centres; (2) to establish free diaphoresis; (3) to facilitate the action of cathartics and diuretics, more especially the diuretic action of digitalis. To the expert diagnostician in renal as in other asthmas, morphine is a therapeutic remedy of the highest value. The writer believes it has a specific effect, as has also belladonna, on the spheno-palatine ganglion.

The spheno-palatine ganglion supplies branches to the nose, throat, soft palate, and Eustachian tube. It possesses a sensory, a motor, and a sympathetic root. It is connected with the pneumogastric and facial nerves, and through its numerous connections an intimate sympathetic relation is established between the throat, nose, ear, larynx, and bronchial tubes. Removal of this ganglion causes a severe catarrhal condition of the nasal mucous membrane. This membrane is continuous with that which lines the eyelids and nasal duct, the throat, Eustachian tubes, the middle ear, larynx, trachea, and bronchial tubes. An irritation or congestion started in the nasal chambers may extend reflexly to the pneumogastric nerve, and cause asthma by bronchial spasm, or the irritation may be so great as to cause, in addition to asthma, acute or subcute catarrhal inflammation of the upper air-passages and bronchial tubes. Opium and its preparations and belladonna have a specific effect in allaying irritation and checking inflammation and secretion in the upper air-passages by acting on the nerve centres, and are highly important not only during paroxysms of asthma, but in the intervals to assist local treatment in allaying chronic irritations and congestions. In connection with quinine and nux vomica they exert a powerful tonic influence on the vaso-motor nervous system. Given in tonic doses three times a day, they prevent the return of the asthma, while the intra-nasal disease is being cured locally. They also prevent acute and subacute catarrhal inflammation in the upper air-passages.

The majority of cases of asthma that I have seen were affected with nasal disease, especially chronic naso-pharyngitis and hypertrophic rhinitis.

Nitroglycerin has an important place in the treatment of the paroxysm and during the intervals, through its effects on the vaso-motor nervous system, the tablets being administered every three to six hours. Chloral hydrate has a decided action in allaying the attacks of asthma. When the paroxysms are very violent and threaten life, chloroform by inhalation is indicated, and proves helpful. In asthma attended by bronchitis and laryngitis, the fluid extract of Grindelia robusta, paregoric, and syrup of Yerba santa, equal parts, every two, four, or six hours, has proven valuable, but at some future time the asthma returns.

Wine of antimony, or ipecac with paregoric, and fluid extract of Grindelia robusta, equal parts, to check and prevent a return of the asthmatic paroxysm has proven a valuable prescription in my hands.

Where there is present a malarial, rheumatic, gouty, or a syphilitic dyscrasia, or mercurial or lead poisoning, the appropriate constitutional treatment for these affections must be given during the intervals of repose. Any gastro-intestinal or hepatic irritation must have its appropriate form of treatment.

As in most asthmatics the general health is impaired, especially in those who have had long-standing chronic intra-nasal irritation and disease, there is an innervation of the vaso-motor nervous system attended with marked anæmia and neurasthenia that demands for its amelioration iron, quinine, strychnia, phosphorus, and electricity.

With three of my patients chromic acid applied to the turbinated processes has checked the paroxysm of asthma almost instantly, and without the previous use of cocaine locally. In one of these cases it was applied to the inferior and middle turbinates (a hay-fever patient); in bronchial asthma, twice to the middle turbinates, and once to the superior turbinated processes.

The local treatment consists in treating intra-nasal diseases. For chronic rhino-pharyngitis, or the latter and laryngo-tracheitis, a two or four per cent. solution of muriate of cocaine is sprayed into the upper air-passages, followed by soothing, non-irritant, mild, astringent, antiseptic, and protective medicines, vaseline being the base, in the form of a spray, every day or every other day *pro re nata*—using it either with DeVilbiss's or Rumbold's spray-producers. Where hypertrophic rhinitis or intra-nasal myxomata, or fibromata, enchondromata, septal spurs or ridges, deflected septums, or foreign

bodies lodged within the nose exist, chromic acid, the snare, galvano-cautery, nasal drill, burrs, forceps, saw or punch should be used in addition to the medical treatment to effect a cure. The vaseline and cocaine spray with some antiseptic should be used after an intra-nasal operation to protect the lesions and tissues, prevent congestion, and render the parts and secretions aseptic. Besides numbing the tissues with cocaine, spiritus frumenti taken internally half an hour before operation, one or two ounces every five minutes, enough to cause partial anæsthesia or intoxication without unconsciousness, has proven a most valuable anæsthetic, and in intra-nasal surgery is to be preferred to chloroform or ether. It can be used with or without cocaine locally; should too much of the latter be used, whiskey would be prophylactic against poisoning.

This paper would be incomplete should inunctions of vaseline and the systematic daily use of massage be omitted.

Concerning the climatic treatment of asthma these facts have been observed, viz.: that asthmatics with chronic rhinitis, hypertrophic, or rhino-pharyngitis, attended with copious secretion, do best in a dry, high, warm, attenuated atomosphere. Those with atrophic rhinitis do best in a moist, warm atmosphere of low altitude. Asthmatics with a mixed form of rhinitis, viz., the hypertrophic and atrophic combined, do best in a warm, moist, low atmosphere, or a high, warm, dry locality, depending upon the predominance of the former or latter variety of disease. Patients have found great relief from asthma and intra-nasal disease by a sojourn in Texas about San Antonio; Orlando, Florida; Thomasville, Ga.; New Mexico, and Southern California—in fact, claim to be well, entirely unconscious of any nasal irritation or disease. One patient claims the dry, dusty atmosphere of Colorado aggravated and increased the nasal disease and made the paroxysms of asthma more violent and their recurrence much oftener. Another patient was entirely free from asthma so long as he lived at Louisville, Ky., but has recurrences on going to the country and remaining a few days.

ON CALF-PEPSIN, AND ESPECIALLY THE GLYCERITE OF CALF-PEPSIN, AS AN ADJUNCT TO A MILK-DIET.[1]

BY FRANK WOODBURY, A.M., M.D.,

HONORARY PROFESSOR OF CLINICAL MEDICINE IN THE MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA, ETC.

FOR a number of years, in treating cases of apepsia in infancy and as an adjunct to a milk-diet at a later period of life, I frequently used rennet-wine, which was acceptable to the patient and which, I believed, had some peptonizing power. I also occasionally met with a communication in the medical journals reporting favorably upon its employment in the digestive disorders of infants. The experiments of Scheffer, published in 1870, in the *American Journal of Pharmacy*, however, demonstrated very conclusively the fact that an alcoholic menstruum was not suited to the preservation of digestive power in a pepsin preparation, and that glycerin diluted with water was the best of all menstrua for this purpose. Last winter, in conversation with Mr. Llewellyn (successor to Hubbell & McKelway), who has had considerable experience in the manufacture of the wine of rennet, I suggested that a solution made with glycerin would be more acceptable, and would prove to be a more active digestive agent than the alcoholic preparations. After several consultations and experiments, we produced this Glyceritum Pepsini Vitulini. The method followed in its manufacture is as follows: The stomachs of healthy young calves are washed clean with running water, the mucous membrane is dissected off, crushed, and treated with glycerin and slightly acidulated water, in which it remains until the pepsin is all extracted; the solution is then filtered carefully, and to it is added a small proportion of the acid phosphate of lime. This was considered a useful addition, because cow's milk is slightly deficient in this constituent as compared with breast-milk, and in order to insure a faintly acid reaction to the finished product. Scheffer found, in the experiments already referred to, that calf-pepsin requires the presence of an acid medium to enable it to exert any digestive action upon albumen.

As milk is increasing in favor, not only as an easily obtained and easily assimilated form of nourishment, but also as a therapeutic agent of no mean value, in inveterate indigestion, in gastric ulcer, diabetes, renal disease, typhoid fever, inanition, as an important part of the rest-cure, and in the perennial baby-feeding problem, the favorable and unfavorable conditions affecting its administration deserve consideration. Quite apart from the results of intentional or accidental adulteration and variations in the quality of the milk, which have been frequently discussed in the medical journals, there may be objections raised by the patient himself, often arising from defective digestive capacity, that may prevent the use of milk, which otherwise would be appropriate to the case. Bartholow[1] has pointed out some of the abuses of milk-diet in therapeutics, and very properly advises against its administration in acute rheumatism, especially in large quantities, on account of the excess of lactic acid introduced into the system by its digestion, which he believes increases the risk of endocarditis, delays recovery

[1] Presented to the College of Physicians, Philadelphia, November 6, 1889.

[1] Journal of Reconstructives, vol. ii., No. 3, p. 10.

and favors the occurrence of relapses. He also states that "In certain disorders of the digestive functions milk causes a sense of discomfort, decided uneasiness, oppression, sometimes even pain, and it prolongs the morbid condition. Such cases may be grouped into two classes: those in which the casein is the offending material; those who cannot properly digest the cream or butter. We find examples of the first class more frequently among children, but they are by no means uncommon in adults. They are detected more readily in early life, because the curds are rejected by vomiting or appear undigested in the stools. Adults unable to digest casein, or who digest it slowly or painfully, have epigastric distress, heaviness and oppression for several hours after meals, stupor and disinclination for exertion coming on after an hour or two and continuing until the offending material has passed well down the intestines." The remedy for digestive disorder occasioned by excess of cream is generally applied with quite unusual consideration for the patient's welfare, by the milk-vender before delivering the article to the customer; when this has been neglected, the excess of cream may be removed by partially skimming the milk before giving it to the patient. This procedure will generally be required in the case of Alderney milk, which often contains too much fat even for infants.

When, on the other hand, there is experienced more or less difficulty in disposing of the casein (and this generally occurs in fever, on account of the deficiency of secretion from the peptic and other glands of the stomach), the administration of pepsin, or an artificial gastric juice, seems the natural resource. Where the diet is cow's milk, it seems reasonable to assume that calf-pepsin, being the proper digestive ferment for this food, ought to be a valuable aid to the treatment, to prevent the occurrence of *embarras gastrique* and to favor the assimilation of the albuminoids of the milk. The dry calf-pepsin, I believe, has been entirely superseded by the more active pepsin of the hog. Scheffer found that the former had only a moderate action upon boiled egg-albumen as compared with the latter; and probably hog-pepsin, when carefully prepared, is preferable for most purposes where a digestive ferment is needed. But where the diet is cow's milk and not hard-boiled eggs or meat, the calf-pepsin would seem to possess especial appropriateness.

Without extending this communication unduly by going into unnecessary detail, I would simply make the following claims, which appear to me to be well founded, for the solution of calf-pepsin in glycerin which I have just presented:

1. The glycerite of calf-pepsin, prepared in the manner described, is a permanent, reliable, and elegant pharmaceutical preparation, besides being the most active form in which to administer this agent.

2. It differs from the wine of rennet, in possessing greater coagulating and peptonizing power, a drachm readily acting upon a pint of milk. Rennet, as stated by Randolph, will not coagulate boiled milk; the glycerite of calf-pepsin does so readily, and forms a soft, delicate curd consisting largely of peptones. In the feeding of infants this property becomes of special importance, in view of the increasing prevalence of the use of sterilized (boiled) milk. In this connection we recall the statement of Kirchner that the difference in digestibility of milk from the cow and that from woman, is wholly due to the large amount of peptones in the latter.

In the case of infants, I usually direct that from ten to twenty drops of the pepsin preparation shall be given fifteen or twenty minutes after feeding; in adults one-half to one drachm is usually added to the milk before it is swallowed, as a matter of convenience. Junket made with this glycerite of calf-pepsin, from either boiled or unboiled milk, is a delicate and easily digested form of nourishment for the sick.

I would mention incidentally, in conclusion, that the preparation may be used to brush over the dry, coated tongue of typhoid fever patients, and to spray the throat in cases of diphtheria, although, as yet, I have not had the opportunity of using it for this purpose. I can, however, speak confidently of its value, in conjunction with sterilized milk, in artificially fed infants, and as a useful adjunct to the milk-diet treatment of various disorders of the stomach and nervous system.

218 S. 16TH STREET, PHILADELPHIA.

MEDICAL PROGRESS.

Hydronaphthol in the Treatment of Tinea Tonsurans.—According to DR. MORGAN DOCKRELL, the most efficient method of treating tinea tonsurans is the following: "Have the head completely shaved, leaving the usual fringe all round; then wash with a 5 per cent. hydronaphthol soap and water as hot as can be borne. After drying the scalp, apply over the affected area a 10 per cent. plaster of hydronaphthol in narrow strips, letting each strip overlap its fellow, taking care that the plaster extends quite half an inch beyond the margin of the diseased patch. Outside the margin of the plaster paint a layer of a 10 per cent. hydronaphthol jelly melted) so as to exclude all air. At the end of four days remove the plaster, when the diseased stumps will be found adhering to it. Repeat the process, applying for one week a 20 per cent. plaster. Again repeat the process, this time applying the 10 per cent. plaster for ten days, when on removal the disease will be found to be cured. During the plaster treatment apply a 5 per cent. ointment to the unaffected portions of the head night and morning. Care should be taken that all articles brought in contact with the head before treatment be destroyed, otherwise reinfection will take place, and the treatment be brought into discredit.—*Lancet*, November 30, 1889.

Injections in the Treatment of Gonorrhœa.—FRIEDHEIM, of Leipsic, in determining the most useful injection for the treatment of acute gonorrhœa, assumes that the material to be injected should destroy the vitality of the gonococcus, and should allay, or, certainly not add to, the already existing irritation of the mucous membrane. In about 1200 cases he has experimented with solutions or mixtures in various strengths, of formamide of mercury, calomel, bichloride of mercury, tannic acid, the salts of zinc and lead, subnitrate and salicylate of bismuth, permanganate of potassium, pyrogallic acid, chloroform water, iodoform, creasote, boric acid, antipyrin, resorcin, salicylate of sodium, naphthalin, and creolin, all of which he found either without effect upon the gonococci, or too irritating. With weak solutions of nitrate of silver, as recommended by Neisser, his results were different, and, after experiments upon 318 patients, he concludes this to be the most satisfactory injection. This treatment, to be satisfactory, should be begun in the earliest stage of the disease. A solution of the strength of 1 : 4000 or 1 : 2000 should be injected from four to six times daily. In about four days the discharge becomes thinner and the cocci fewer. After this several of the daily injections of silver solution may be replaced by solutions of sulphate of zinc or boric acid, though at least one daily injection of the nitrate should be used for several weeks.

In a few patients the urethra will be found so sensitive that the silver solution in the strength mentioned will cause considerable pain, and in such the strength may be reduced or each injection preceded and followed by one of boric acid solution. Gonorrhœa situated in the anterior urethra Friedheim has found to be very favorably modified by this treatment, the duration shortened, and complications prevented. Gonorrhœa of the posterior urethra he believes should not be treated by injections of any kind.—*Therapeutische Monatshefte*, November, 1889.

Sweating of the Feet.—According to the *British Medical Journal*, experiments on 18,000 cases in the German army have conclusively proven chromic acid to be the most satisfactory application for sweating feet. The feet should be washed, and when dry a five per cent. solution of the acid applied with a brush. Two or three applications are, as a rule, sufficient, though in some cases the treatment must be repeated in two or three weeks.

Treatment of Tonsillitis.—DR. HABERKOM, in the *Centralblatt für Chirurgie*, recommends salicylic acid in the treatment of acute tonsillitis. "The best and simplest mode is to apply the powdered acid directly by means of a rather large camel's hair pencil, which may be slightly moistened. In this way it is brought directly in contact with the diseased surface, and but few applications are necessary.

When the tonsils are covered with a thick mucous coating—which may be diphtheritic—it is necessary to remove it previously, and the following liquid, to be also applied with a brush, acts extremely well:

Pepsine	30 grains.
Dilute hydrochloric acid	℥j.
Water	℥v.
Glycerin	℥jv.

The coating is quickly dissolved (digested) by this solution.

Beside applying the acid locally, it is advisable to give it internally at the same time, thus:

Salicylic acid	30 grains.
Mucilage of acacia	℥j.
Simple syrup	℥ss.
Water	℥jvss.—M.

Dose.—A tablespoonful every two hours.

In the more chronic forms it is well to pencil the tonsils with:

Tannin	15 grains.
Tincture of iodine	2 drops.
Glycerine	℥v.
Water	℥j.

For the prompt dispersal of threatened quinsy, apply with a brush three times a day the following solution:

Tannin	15 grains.
Tincture of iodine	3 drops.
Carbolic acid	℥ss.
Glycerin	℥v.
Water	℥ijss.

—*Provincial Medical Journal*, December, 1889.

Preparation of Aseptic Sponges.—PROFESSOR KEEN recommends the following method of preparing sponges for surgical operations:

1. Beat with wooden mallet, to get rid of sand and calcareous matter.
2. Soak in warm water for twenty-four hours.
3. Soak in solution of potassium permanganate (℥j to gallon) twenty-four hours.
4. Wash thoroughly in warm water.
5. Place for one minute in—

Sulphite of sodium	℥x.
Hydrochloric acid	℥j.
Water	gallon j.

6. Wash in water and place in 20 per cent. solution of carbolic acid.—*College and Clinical Record*, December, 1889.

Treatment of Psoriasis at Lyons.—The following is the outline of Gaillcton in the *Gazette Hebdomadaire* of December 13, 1889. The indications are: 1, cleanse the surface; 2, modify the local state; 3, prevent recidivity. For the first indication prescribe alkaline baths accompanied by frictions with soap to remove the scales. In the treatment of the diseased surfaces Gailleton prefers local application of chrysarobin or pyrogallol. The first is used in a pomade in the proportion of 1 to 10, and employed with frictions. The pyrogallol salve should be of the strength of 1 to 5 in psoriasis vulgare. Its use requires management since it may inflame the skin or provoke poisoning by absorption. It is also useful in the acute psoriasis of a scarlatiniform type.

The general and preventive treatment: Arsenic should be given in the acute stages, beginning with Fowler's solution, in the dose of five drops, augmenting it to twenty [small doses would probably be more safe.—ED.], or arseniate of soda may be given in syrup.

To complete the cure, use simple baths every day for one, two, or three hours. This is an important part of the treatment.

The Treatment of Influenza.—In the *Revue Générale de Clinique et de Thérapeutique* of December 12, 1889, HUCHARD gives the following outline of the treatment of this troublesome affection, dividing it into that devoted to the benign form and those cases which present the more serious aspect. In all the past epidemics of this disease one of the principal evidences of its presence is the nervous adynamia. Against this state all our efforts should be directed, and for this reason quinine, alcohol, and similar drugs should be given, or, if the state be grave, injections of ether and cardiac stimulants. The quinine is indicated since it controls the fever. The dose should be from 7 to 15 grains in the morning, and 15 grains of antipyrin at night. Where no antipyretic is needed, small, frequently repeated doses of quinine are to be used as follows:

Sulphate of quinine . .	30 grains.

Make in 20 powders. Take 4 a day, or 1 every four hours.

In those cases where the disease is accompanied by rheumatic and neuralgic pains the following should be used, the soda quieting the stomach:

Antipyrin	150 grains.
Bicarbonate of soda . .	75 "

Make into 10 powders, and take 1 powder every four hours in a little sweetened water, between or immediately after meals.

If there is any reason why antipyrin is not successful, use phenacetin, 4 grains every three hours.

When the rheumatism is severe, use

Salol	75 grains.

Make into 10 powders. Take 5 a day. [This we think too much by half.—ED.]

When the disease affects the pulmonary mucous membrane the condition often becomes most grave, and marked adynamia asserts itself. Stimulants, tonics, and good foods should be given, particularly milk. Diuresis should be increased to eliminate the poisons from the body, and this is particularly true in those cases where there is renal or cardiac dyspnœa. If collapse ensues, heat should be applied to the body and caffeine and digitalis given hypodermically. In those cases where the disease chiefly affects the gastro-intestinal tract, castor oil, or some similar purge, should be administered, and followed by salicylate of bismuth, or magnesia, naphthol, iodoform, or like drugs.

Dengue Fever.—Numerous observations are being made upon dengue fever in Eastern countries, where ample opportunities have been afforded by the epidemic which has been prevalent for some months. According to the *Revue Médico-Pharmaceutique* of Constantinople, although its microbe is as yet undiscovered the disease should be classed among the acute infectious maladies, resembling acute rheumatism and allied diseases.

As to the contagiousness of dengue fever, the writer has never observed or read a striking proof that this disease is propagated from person to person, as is the case with variola, while there are reasons for believing that its method of propagation is identical with that of Asiatic cholera and typhoid fever.

Dengue is not contagious; it is not miasmatic, like malaria, but a miasmatico-contagious disease, like Asiatic cholera, typhoid fever, and epidemic cerebro-spinal meningitis.

The poison is prepared in infected soil, and received by means of water and emanations.

A rocky soil, according to the theory of Pettenkofer, is highly unfavorable to the development of dengue.

Dengue has been believed to be contagious from the fact that several persons in a household are apt to be attacked by it. There are instances to the contrary.

Dengue attacks both sexes and every age without the least predilection. Very few persons are immune. The epidemic may become pandemic and attack even domestic animals.—*Abstract of Sanitary Reports*, December 20, 1889.

Formula for the Administration of Naphthalin.—DR. TICHBORNE, in the *Medical Press and Circular*, December 11, 1889, gives the following formula for the administration of naphthalin.

Naphthalin	16 grains.
Expressed oil of almond .	4 drachms.
Acacia	1 drachm.
Syrup of orange . . .	1 "
Water	3 drachms.

The naphthalin should be thoroughly mixed with the oil of almond before adding the remaining ingredients.

Subcutaneous Administration of Iron.—PROFESSOR ROSENTHAL, of Vienna, advocates the hypodermic administration of iron in the cases of delicate neurasthenic persons who suffer, as such often do, from atonic dyspepsia. Here even small doses of iron taken by the mouth will sometimes produce disorder of the stomach. In severer forms of disease, such as pernicious anæmia, malarial cachexia, and the graver forms of leukæmia, there does not appear to be any advantage in the employment of the hypodermic method of administering iron. Two new preparations are recommended by Professor Rosenthal for hypodermic use—viz., the peptonate and the oleate of iron. He states that he has never seen bad results follow subcutaneous injections of these preparations, and he explains the fatal consequences that have occasionally been reported as following injections into vascular tumors of the head, by the fact that the vessels composing such tumors are generally closely connected with the veins of the dura mater. He has frequently seen venous enlargements in the legs shrink after being injected with dilute perchloride of iron, no dangerous symptoms ever ensuing.—*Lancet*, December 14, 1889.

Prescription for Tympanitis.—The following formula for tympanitis is quoted in the *Deutsche medicinische Wochenschrift*, November 28, 1889:

R.—Naphthol Magnesium carbonate Pulverized charcoal . .	āā 75 grains.
Oil of peppermint . . .	10 drops.—M.

Divide into 15 powders, of which one is to be given when required.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 4, 1890.

POLITICS IN MEDICINE.

THE NEWS has hitherto forborne to comment upon the ignoble strife which the Mayor of Philadelphia has seen fit to wage with the forlorn and friendless sick paupers of the city. We could not believe that a majority of five citizens, selected as fit to act in the delicate and responsible position of members of a "Board of Charities" could be found who would prove faithless to their trust, and oblivious to the welfare of those whom they were bound by every consideration of duty and honor to protect.

The idiosyncrasies of our Chief Magistrate are so generally understood that we presume no one expected that the unreasoning wrath of his wounded vanity would be satisfied without victims, but it was not supposable that he would find three willing and obedient tools in the Board of Charities to carry out his commands. The only question which the Board had to consider in renewing the staff of the Philadelphia Hospital was the interest of the unfortunates whom poverty and sickness have thrown upon the tender mercies of public charity. They have no political pull; they have no opportunity of making their wants and miseries known to his Honor the Mayor over the whist-table: they are simply dumb sufferers who must submit in silence to their fate. If their ailments are treated with knowledge and skill they may recover and become useful citizens again; if they are treated ignorantly and are used as *corpora vilia* to educate young men and advertise medical colleges, they can only die in silence, and those dependent upon them can starve. To talk of dividing "patronage" of this kind among medical institutions is far worse than the worst political profligacy of office-brokerage, for the spoils to be apportioned are the agonies of the city's poor.

No more difficult or weighty duty could be imposed on five men than the selection of the thirty-three members of the hospital staff, on whom devolves the care of the sick paupers in the population of a million souls. With a conscientious man such a duty could only be discharged after the most careful and minute investigation into the acquirements and fitness of each aspirant and a selection based solely upon the interests of the unfortunates who are to be cared for. Yet when the Board assembled and a list of candidates was put in nomination, Mr. McMurtrie vainly begged for a postponement to enable him to make some inquiry as to the comparative merits of competitors whose names were wholly unknown to him. The voting was commenced forthwith in spite of his protests and went on with a regularity and precision which showed that the slate had been made up by a power behind the throne, and that the Board was there simply to register its decrees.

In the name of the profession and of common humanity we protest against such political management of a great public charity, and we do this irrespective of the comparative merits of the gentlemen who were dropped and of those who were elected to their places. We are not criticising the latter, but the methods by which politicians have used them to establish political autocracy in the management of the hospital, and to proclaim that subserviency to the wishes or whims of the Mayor is the condition upon which members of the profession can have the privilege of ministering to the sick poor. If good men can thus be used this year, indifferent men or bad men can be so used next year. It becomes a matter of chance or caprice, in which the real interests concerned—those of the patients of the hospital—are the last to be considered.

REVIEWS.

Cyclopædia of the Diseases of Children, Medical and Surgical. By American, British, and Canadian Authors. Edited by John M. Keating, M.D. Vol. II. 8vo., pp. 1066. Illustrated. Philadelphia: J. B. Lippincott Company, 1889.

The second volume of this Cyclopædia more than fulfils the promises held out by the first, and we regret that limited space forbids mention of many articles deserving of high praise.

Part I., Diseases of the Skin, is written entirely by American authors, the names of Hyde, Hardaway, Bulkley, Van Harlingen, I. E. Atkinson, and Stelwagon being sufficient to indicate the worth of the articles. Perhaps the most admirable of these are Eczema, by Van Harlingen, and Parasitic Diseases, by Stelwagon, which are discussed in a manner peculiarly valuable to the general practitioner.

In Part II., Constitutional Diseases and Diseases of Nutrition, are found the most elaborate and interesting articles in the volume. Particularly praiseworthy are the exhaustive essays upon Scrofulosis, Tuberculosis, and Rachitis, respectively contributed by Ashby, Jacobi, and Barlow and Bury. Tuberculosis exhibits the usual broad views and extensive reading of its author, who, never content with a simple statement of others' views, invariably supplements them with his own suggestive comments. Dr. Jacobi seems to accept unhesitatingly the communicability of tuberculosis, and as a prophylactic measure insists upon the importance of sterilizing all milk given to bottle-fed children.

Rachitis is most exhaustively studied by the joint authors, who quote extensively from the work of Kassowitz, and accept his view that the essential morbid change in rickets is increased vascularization of the bone-forming tissues; certainly the most satisfactory explanation of rachitic phenomena, and with abundant evidence of truth. Though followers of Kassowitz in pathology, we are disappointed at learning that the authors have had no experience with phosphorus, the use of which, in this disease, he so strongly advocates. The last work, and not the least important, of the late Dr. Fothergill, is his contribution to this section on the Urinary Diatheses: Oxaluria, Phosphaturia, Lithuria. It is written in the well-known attractive style of its prolific author, and teems with suggestive thoughts.

In Part III., Diseases of the Respiratory Tract, we find papers on nasal diseases by Mackenzie, of Baltimore, MacCoy, Morgan, Delavan, Bosworth, and Seiler; on diseases of the pharynx by Ingalls, Robinson, and Allen; on laryngeal diseases by Sajous, Morell Mackenzie, Northrup, and Wharton. We are glad to note the important position here assigned to the upper respiratory tract, which is so constantly neglected in the management of children, to their discomfort and suffering in after years.

Excellent and clear advice is given by Dr. Northrup in his eight pages on Intubation.

Tracheotomy, by Dr. Wharton, is a most carefully prepared and elaborate essay upon the subject, more satisfactory in many respects than the somewhat similar work of Lefferts. Among the indications for operating in diphtheritic laryngitis, Wharton esteems the ability or inability of the patient to sleep. If able to sleep for a few hours at a time, he believes operation is not usually required. This doubtless is, in many cases, a valuable guide, but its value should be estimated in connection with other symptoms, and septic stupor should not be mistaken for true sleep.

Among diseases of the lungs Croupous Pneumonia is discussed by Francis Minot in an article which, though short, is full of good sense. The author decries the frequent use of aconite and quinine in this disease, believing the former dangerous, the latter worthless.

Bronchitis, by F. Gordon Morrill, is, to us, not a very satisfactory contribution, particularly in the matter of treatment, where he gives numerous conventional formulæ, some variety of syrup being the basis of each. Syrups, we believe, are abominations, interfering with digestion and thus doing more harm than good. Much the same may be said of flaxseed and slippery-elm tea, of which the author advises the administration in large quantities. We regret that no mention is made of inhalations, which with bronchitis in children have in our hands rendered excellent service. Other articles on pulmonary diseases are, Emphysema, Asthma, and Hay-fever, by Shattuck; Phthisis, by Jacobi; Pleurisy, by Whittier; Empyema, by Cabot; Diseases of the Thyroid and Thymus, by Rex, and Affections of the Mediastinum, by Edwards, all of which are good. The latter is drawn largely from Hare's Fothergillian Prize Essay, which, however, could hardly be avoided by the author, and which in no way detracts from the value of the article.

Part IV., Diseases of the Circulatory, Hæmatopoietic and Glandular Systems, is opened by DaCosta in a rather brief article, giving the impression of hurried preparation, on Functional Disorders of the Heart. Osler gives an interesting *résumé* of Congenital Affections of the Heart.

Bruce contributes excellent papers upon Enlargement of the Heart and upon Myocarditis and Cardiac Aneurism. Sansom's article on Chronic Endocarditis—Valvular Disease—will naturally be one of the first turned to by those interested in cardiac diseases, and in it they will find no cause for disappointment. This recognized authority has here written a clear and practical description of chronic endocarditis, its sequelæ, and treatment.

In Part V., Diseases of the Mouth, Tongue, and Jaws, we find articles upon Diseases and Care of the Teeth, by Darby; Congenital Defects and Deformities of the Face, Lips, Mouth, Tongue, and Jaws, by Roswell Park; Diseases of the Mouth, by Allchin; Harelip and Cleft Palate, by J. Ford Thompson; Injuries and Diseases of the Jaws, by Mears, all of which are thoroughly in keeping with the character of the volume, being clear, concise, and practical.

We cannot close this notice without reference to the illustrations, which are more numerous and of better execution than those of Volume I.

Dr. Goodell's Address before the Ontario Medical Association.—Dr. William Goodell has been requested by the Ontario Medical Association of Canada to deliver the address at the annual meeting of the Association, to be held in Toronto, June, 1890.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, November 4, 1889.

THE PRESIDENT, D. HAYES AGNEW, M.D., IN THE CHAIR.

DR. THOMAS G. MORTON exhibited

SPECIMENS OF ASTRAGALUS REMOVED FOR EQUINO-VARUS,

and said that since the last meeting of the Academy he had removed the astragalus in several cases for equino-varus, the youngest patient being a child of eighteen months, who had been treated for ten months with daily massage, and under ether the feet had been thoroughly stretched, and a carefully moulded splint applied. It was impossible to bring the foot to a right angle with the leg from the presence of the astragalus, which was found to be anterior to the tibia. An incision two inches in length was made commencing back of the fibula and continued forward directly over the prominent astragalus, the posterior part of which was found to be in front of the tibia. The astragalus in both feet were excised, and the tendo-Achillis divided; perfect position was at once obtained without effort. The bones removed were so different in shape from the normal bone that they were shown to Professor Leidy, who wrote that "the two specimens of bones submitted to my examination a few days since are so altered from the normal form that I utterly failed to recognize them as being astragalus."

Dr. Morton also showed similar specimens from two other and older cases recently operated upon.

At the last meeting of the Academy the question of the condition of the ankle after the excision of the astragalus was briefly discussed; in the cases which he had had, the joint motion before operation was greatly interfered with and could not be increased from the presence of the astragalus in front of the tibia. On removing the astragalus the foot can at once be placed in a normal position and retained so without any effort, or the use of a brace, and all the cases so operated upon have required but a single dressing, generally removed about the third week. In cases where stretching and tenotomy fail, and in cases of ankle malposition, he advocates very early excision, because the immediate and complete rectification of the deformity permits better development of the limb.

DR. MORTON next reported a case of

FRACTURE OF THE LOWER END OF THE RADIUS AND ULNA.

On November 1st, a man, aged thirty-five, was admitted into the Pennsylvania Hospital with a compound depressed fracture of the skull and facial bones, having been struck by a locomotive; there was also a fracture of the lower part of the forearm with marked deformity; the patient was severely shocked, and died without reacting. The appearance of the deformity of the forearm fracture was well shown in a photograph which was presented, and the lines of fracture in the dissected specimen. There was an irregular transverse fracture of the lower end of the radius half an inch from the carpal articulation; at the outer side of the lower fragment there was also a vertical fracture extending into the joint a quarter of an inch from the ulnar attachment; the lower fragment was found above and resting upon the upper fragment, presenting the typical "silver fork" deformity of Velpeau.

DR. J. EWING MEARS then reported a case of

STAB-WOUND OF THE THORAX, INVOLVING THE PERICARDIUM, DIAPHRAGM, AND STOMACH.

On the evening of August 10, 1889, while the patient and his brother were engaged in an altercation, the latter threw at him an open penknife. The blade struck the patient upon the chest from above downward, penetrating the intercostal space between the sixth and seventh ribs and passed inward, downward, and backward, and was buried in the tissues up to the handle. It remained thus until the patient removed it some minutes later. But for some slight pain, at the time of injury, and some temporary respiratory embarrassment, he experienced no symptoms of any moment. After the removal of the knife he went home, and the wound was dressed with *isinglass plaster*. That night he slept fairly well, but the next morning noticing a protrusion from the wound he was taken to St. Agnes' Hospital. On examination at the hospital by Dr. Vincent, Resident Physician, a small piece of omentum, about one and a half inches long and three-fourths of an inch wide, protruded from the wound. The omentum presented no signs of strangulation. The patient complained of no pain, but there was some difficulty in respiration. A probe was introduced into the wound, and its direction noted to be downward, backward, and inward. The protruding omentum and surrounding tissues were washed with bichloride solution 1 : 2000, and a dry bichloride dressing applied.

On the following day Dr. Mears reduced the omental hernia and closed the wound with two deep sutures of carbolized silk and dressed it with dry bichloride gauze (1 : 1000). During the operation no pain of any moment was noted, and upon its completion the patient was ordered morphine ¼ grain at 6 P. M., and three ounces of milk every four hours.

12th. Patient felt very well, and there was but slight increase of the pulse rate; no pain and no fever. Passed a fairly good day, and about midnight had a stool, arising from his bed for that purpose, which was hard, lumpy, and caused him to strain.

13th. Felt quite well until 7 A.M., when he was given two ounces of ice water by the nurse, and soon after complained of feeling faint. A cold sweat followed; but these symptoms passed away. At 8 A.M. he was given two ounces of milk, and in fifteen minutes he complained of nausea. At 8.30 A.M. he vomited a little blood, which was dark and mixed with milk. Again he vomited, but this time about four ounces of uncoagulated bright blood, and soon after he vomited about two pints more—some bright red, but the most dark and coagulated. His pulse could scarcely be perceived, his extremities became cold, and his respiration very shallow. He was given morphiæ sulphatis hypodermically and artificial heat applied to the extremities. The fluid extract of ergot was also given, but in a few minutes he became nauseated and vomited again, the vomited matter consisting entirely of bright blood. The amount

thrown up was about one pint. This was his last attack of vomiting, and it was about three hours before he began to react. By 6 P. M. he was in comparative comfort again.

13th. Several bloody stools were passed, each more than four ounces.

14th. Several small, bloody stools.

15th. No movement of bowels.

18th. Passage in the night; contained very little blood.

19th. Dressings removed, and wound found in good condition; no signs of inflammation; sutures removed and lips of wound held together by adhesive strips over which dry bichloride gauze and a roller were applied.

20th. Felt quite well; no pain; took food by the mouth for first time since the hæmatemesis and retained it.

21st. Troubled with slight colic but passed gas freely, and was thus relieved; bloody stools no longer present.

22d. Given an enema, and bowels moved twice; felt no pain, and stools were natural, quite copious and well formed.

30th. Dr. Mears made an examination of the wound and described it as situated between the sixth and seventh rib in the line of the left nipple one-fourth of an inch from the junction of the costal cartilage and three inches from the middle line.

The cicatrix was obliquely placed from above downward and from without inward.

The wound was entirely united. The cicatrix measured one-half an inch in length.

The foregoing history presented several points of interest with reference to the parts involved and the occurrence of the hemorrhage forty-eight hours after the receipt of the injury. The position of the wound and the direction taken by the knife-blade indicate penetration of the thoracic wall, pericardium, and diaphragm. The vomiting of blood and its passage by stool establish the fact that the wall of the stomach was incised at a point which involved section of a bloodvessel of some size. The presence of the coagulated blood in the vomited matter demonstrates the existence of hemorrhage at a time previous to the act of emesis, which was held in check by the enforced rest of the patient. Prior to the receipt of the injury the patient had indulged in copious draughts of beer, which distended the stomach and brought it into close contact with the diaphragm. The wound of the pericardium was evidently but slight and at its border of attachment to the diaphragm.

The prompt cessation of the hemorrhage under the treatment adopted justified its continuance and the withholding of operative procedures. For six days following the hæmatemesis alimentation was maintained exclusively by the rectum, beef-tea and brandy being administered at intervals of four hours. Morphine was given hypodermically night and morning in one-sixth and one-eighth grain doses. At the expiration of four weeks the patient was discharged cured.

CORRESPONDENCE.

DETROIT.

To the Editor of The Medical News,

Sir: At the last regular weekly meeting of the Detroit Medical and Library Association, the President, Dr. Maclean, exhibited several very interesting pathological specimens. One, an osteo-sarcoma involving the left scapula, the entire bone being excised, and the patient, a young man, making a rapid recovery, with a very useful arm.

He also reported the case, and exhibited the specimen, of resection of the head of the humerus, from a young man, who was injured by a base-ball striking him on the right shoulder. The operation of resection was followed by a rapid and extensive development of bony material, suggesting osteo-sarcoma. The patient died in a few weeks from exhaustion.

The third specimen was a very vascular and fibro-cystic tumor, unlike nævus, of the cheek, which, subsequent to removal, gave great and alarming trouble from recurrent hemorrhages. The patient is at present quite well.

An adenoma of the breast removed without interference with that gland was also exhibited from a girl, aged sixteen years. No recurrence.

The last exhibit embraced two portions of a femur, which had been operated upon for non-union after fracture associated with dislocation of the head of the same upon the dorsum ilii. The operation for non-union was not successful, and symptoms developed which necessitated amputation of the thigh. The patient recovered. The non-union in this case was attributed by the exhibitor to the very severe shock received by the bone —a heavy derrick having fallen upon it—and this he considers one to be added to the many causes for non-union in fractures.

A matter which has come to my notice affecting the medical profession is a case of gross falsifying upon the part of a medical institution.

Dr. W. E. Eggleston, in a special article on "Our Medical Colleges," published in the *Journal of the American Medical Association* for May 25, 1889—in a special edition of 75,000 copies scattered broadcast throughout the United States—endeavored to convey a true idea of the work required of students in every college in the United States and Canada.

In spite of the fact that every effort was made to get a truthful statement from each medical college—by even writing to them in several instances—I find, upon investigation, that the replies in answer to most important questions, as published, from the University of Michigan are absolutely false in eight instances.

In the first place, they claimed 800 beds at command for clinical instruction when, as a matter of fact, there were at that time 66 beds for patients and 4 more being repaired, making 70 beds in their possession, which by no error could be changed into 800.

Answers to the following questions were requested:

1. Is each student required to examine and prescribe for patients in a hospital?

2. Actual clinical work done by the student?

3. Is each student required to take a practical course in operative surgery, bandaging, and minor surgery?

4. Is each student required to practise on the manikin or living subject, or both, in obstetrical diagnosis and treatment?

5. Is each student required to examine gynecological cases and to prescribe or treat them under direction of a teacher?

6. Physical diagnosis. Is each student required to

practise this on the living subject, under the direction of a teacher, or is he simply told how to do it?

7. In the final examination on practice of medicine, is the candidate required to diagnose the disease of a living subject, in the presence of one or more teachers and the patient, discuss the case and indicate treatment?

8. Is the same true as regards surgical examination?

9. In the final anatomy examination, is the student required to demonstrate any part of the body?

The answers published were "yes," when, as a result of investigation, it is clearly proven the replies should be "*no*".

The elasticity of the assertions published from our medical colleges is to be greatly regretted, and we are always ready to make allowances for their announcements; but when an institution, and a State institution at that, makes such direct false assertions in reply to questions put for the benefit of the medical profession, that institution is deserving of the severest censure. No words can be too harsh for such deceit.

The statement in your extract from the Ann Arbor *Courier*, in THE MEDICAL NEWS of November 23, 1889, is incorrect. Dr. Maclean was appointed to the professorship of surgery in the Michigan State University in 1872, and resigned in 1889.

The patriotic move to have the Stars and Stripes floating over our school-houses has extended itself to the Detroit College of Medicine. Recently, a beautiful flag was unfurled from the flag-staff of the above College with elaborate ceremonies on the part of the students, interspersed with college songs, cheers and a tiger.

The Detroit Board of Health has issued a circular letter to the effect that all typhoid fever cases will henceforth have to be reported to the Health Officer, according to law, but rules it "not necessary to placard the houses where such patients are sick."

ANN ARBOR.[1]

To the Editor of THE MEDICAL NEWS,

SIR: In reply to the above, the animus of which is apparent to all who are acquainted with the Medical Department of the University of Michigan, I wish to be as brief as possible. The number of beds in the hospital is 70, but it has, for a number of years, been necessary to use beds in private houses near by; and this fact must have been known to the writer of the above. The number of patients accommodated outside of the hospital was in 1881 and 1882, 498; in 1883 and 1884, 530; in 1884 and 1885, 351. The exact numbers are not given in the remaining reports, but the above may be taken as fair averages. Our Secretary answered the question, "How many beds are devoted to clinical instruction?" by the number 80, which was an under-statement and not an exaggeration. By a typographical error another cipher was added. This was so evidently an error that no one thought of correcting it. Now, in reply to the other questions:

1. Students are required to prescribe for the patients in the hospital, and this has been the practice from the time when the hospital was opened. Every operation or other case in surgery is assigned to two members of the senior class, who, under the professor or his assistant, do all the dressing and conduct the after-treatment of the case. The same general method of instruction is followed by the professor of clinical medicine and his assistant. In ophthalmology students are called upon to examine and diagnose the case. Then, if an operation is necessary, the patient is anæsthetized and a section of the class is invited to stand closely around the table, while the assistants required in the particular case are selected from the section. The after-treatment is assigned to two seniors, who are required to visit the patient twice a day. There is also practical instruction given in the use of the ophthalmoscope and the laryngoscope in a dark room.

2. This is answered above.

3. Practical courses in minor surgery and bandaging are given; if they have been omitted during any year it lies with the then professor of surgery to explain. I have before me a report given by Dr. Hendricks, assistant to the professor of surgery two years ago, in which he states that he devoted over forty hours to minor surgery, with nearly thirty hours to surgical anatomy and operations on the cadaver with the senior students of that year.

4. The students not only witness confinements, but after properly disinfecting their hands, make digital examinations during the several stages of labor. If any member of the class of '89 failed to witness a case of confinement, it was not for want of opportunity. The professor of obstetrics tells me that "every senior last year who had not had such experience elsewhere, attended a confinement in the hospital."

5. Gynecological cases are examined before sections of the class, and so far as can be done, the students make these examinations and diagnose the case.

6. Students are drilled practically in sections, daily, in auscultation and percussion. This embraces the study of both healthy and diseased organs.

7. Every senior student is required to examine, diagnose, and prescribe for patients before the professor and members of the class, and the correctness with which this is done is an important factor in deciding the vote which the student receives when he comes up for graduation.

8. Surgical examinations are required, as has been shown above. Whether or not this was done last year I cannot say. It is to be presumed that it was done. In his report to the Board of Regents in 1882, the professor stated: "Four hundred surgical cases passed through my hands during the session now closed. Of these, a large proportion was presented to the class on several different occasions, for the purpose of illustrating the different forms or phases of their ailments, and also to illustrate the effects of treatment. The dressing and after-treatment of these patients have furnished the members of the graduating class with much valuable practice." I have no reason to suppose the practice has differed in other years. After enumerating some of the operations, he says: "From this partial list it will appear that almost every department of surgery has been illustrated by characteristic cases."

9. This question, as stated by your correspondent, is somewhat indefinite; but I will say that every student must have dissected and demonstrated every part of the body before presenting himself for graduation.

[1] In view of the fact that THE MEDICAL NEWS cannot be the bearer of any news which seems to be born of misunderstanding, the following reply has been sent from the University of Michigan after reading the Detroit letter.

Now, Mr. Editor, the answers given to the questions of Dr. Eggleston by the Secretary of the Medical Faculty of the University of Michigan were true and just. The Medical Department has been in existenee for a great many years; the graduates are numbered by thousands; they are located in every section of the country; by them the past work done here may be judged. As to the work now being done, I will say that the hospital, clinic rooms, lecture rooms, and laboratories are open for the inspection of any medical man.

C. L. Ford, *Dean.*

TREATMENT OF INFLUENZA.

To the Editor of The Medical News,

Sir: As an item of interest, the quickest relief from influenza which my patients obtain is through the use of pine needle cigars and cigarettes. I find they will act as a preventative, and once the disease has instituted proceedings they act like magic. Any one can make the cigarettes. I have no hesitancy in recommending their use, as nothing is used in their manufacture but the fresh pine needle and the best of tobacco. A non-smoker can inhale with no unpleasant effect.

Yours respectfully, Harry Neafie, M.D.

Freehold, N. J.

OBITUARY.

Dr. James H. Hutchinson, of Philadelphia, died, after a few hours of illness, on Friday morning, December 27, 1889. Descended from a prominent physician of this city, Dr. Hutchinson inherited the love of his profession which he evidenced in his devotion both to its practice and advancement. At once one of the most learned writers and most conservative of advisers, he occupied a position representing the best admixture of progress and clearness of thought that could be turned to by the general practitioner needing a consultant, and in consequence, one of the last professional acts in his life was to go out of town to see a serious case of illness for another physician.

Dr. Hutchinson graduated in arts from the University of Pennsylvania in 1854, and, after spending a year abroad, began the study of medicine, graduating, in 1858, from the same institution which gave him the degree of A.B. He at once became resident physician to the Pennsylvania Hospital, and, after a service of eighteen months, went to France and Germany, where he devoted himself to dermatology, being part of the time under Hebra. On returning to America, he became physician to the Children's Hospital, a position which he held at the time of his death. In 1862, he was made physician to the Episcopal Hospital, where he served constantly till elected to the Pennsylvania Hospital some years later. At the time of his death he was Vice-President and Honorary Librarian to the College of Physicians, a Trustee of the University of Pennsylvania, a Director of the Philadelphia Library, a Manager of the Pennsylvania Institution for the Blind, of the University Hospital, and a Vestryman of St. James Church, showing in this way his great interest in all measures devoted to the improvement of his fellow-man. At one time Dr. Hutchinson was Secretary, then Treasurer, and finally President of the Pathological Society. His most widely known contribution to medicine is the article on typhoid fever in Pepper's *System of Medicine*, which has been universally recognized as one of the most masterly studies of the disease extant.

The following resolutions, passed by the College of Physicians at a special meeting, are indicative of the admiration of his professional brethren:

"The College of Physicians of Philadelphia has heard with profound regret of the death, after only a few hours' illness, of its Vice-President, Dr. James H. Hutchinson, and hereby records its profound sense of the loss—to human eyes irreparable—thus occasioned, not alone to its own body, but as well to the whole medical profession of the city and vicinity, and to the entire community.

"Still in the prime of life, with skill and knowledge broadened and confirmed by wide and ever-growing experience, Dr. Hutchinson shone prominent both as a faithful and trusted family physician, and as a consultant whose advice and assistance were largely sought for and highly prized by his fellow-practitioners, all of whom recognized both the value of his counsel and the uniform candor and conscientious honesty with which it was bestowed.

"A Fellow of this College for more than a quarter of a century, he served it in council and committee-room with a zeal and fidelity which are amply witnessed by its transactions and by the records of its library, and which but met with its just recognition in his unanimous election to the honorable office of Vice-President.

"A scholarly and accomplished writer, an able clinical teacher, a skilful and judicious practitioner, well exemplifying the highest and best type of the practical physician; a high-minded, honorable Christian gentleman, tried and true in all the various relations of an active, busy life—his death leaves a gap which can never be filled; a precious memory which will endure long after those who now grieve for him shall themselves have passed away forever."

NEWS ITEMS.

St. Luke's Hospital Fund.—St. Luke's Hospital, New York, is endeavoring to raise $50,000 to pay its indebtedness. Part of the money, $34,000, is due the treasurer for funds advanced by him to the institution. This indebtedness has been increased by the growing demands on the hospital. About $37,000 has already been secured, and it is hoped to obtain the rest before many weeks. The hospital receives no aid from the city.

Obituary.—Dr. Charles H. Nichols, the Superintendent of the Bloomingdale Insane Asylum, died at his home, on the asylum grounds, December 16th. Dr. Nichols spent last summer in Europe studying the management and construction of foreign asylums, and since then has been in failing health. He was graduated from the University of New York and from the University of Pennsylvania in 1843. Since the latter date he has devoted himself to the care of the insane. In 1852 he was appointed by President Fillmore to superintend the construction of the Government Hospital for the Insane, resigning his position at the Bloomingdale Asylum for that purpose. In 1877 he again assumed the management of the latter institution.

Dr. David Prince, one of the oldest and most successful surgeons of Jacksonville, Illinois, died on December 19th from pneumonia. Dr. Prince had twice been a delegate to the International Medical Congress.

Fatal Result of Extension in Locomotor Ataxia.—Another fatal result from extension for locomotor ataxia has been reported by Dr. C. Bosari, of Modena. At first the treatment appeared to reduce the ataxic symptoms, but a leptomeningitis supervened followed by death. Dr. Bosari is not clear in his own mind concerning the causal relation of extension to the unfortunate results.

Faith-healers Heavily Fined.—The "new evangelists," as the Scandinavian sect of the faith-healing believers is called, have been heavily fined, in Brooklyn, for disobedience of the laws and ordinances governing the treatment of minors sick with contagious disease. Three persons, on four charges, were called upon for $450 in fines, or to go to jail. Some have accepted the latter alternative, and others say that they will follow rather than give their children medicine or observe the isolation orders of the Board of Health. In regard to contagious diseases, these people act on the principle that if "the Lord" causes a disease to be of a communicable nature, it is right that it should spread, and that if children die from such diseases, "the Lord is simply taking home his own."

A Courageous Ambulance Surgeon.—Ambulance Surgeon Mead, of St. Mary's Hospital, Brooklyn, was called to an elevated road accident, and found that the mangled, yet conscious, patient, had fallen and been caught under a locomotive. The surgeon administered a hypodermic to the injured man before the latter had been disentangled from the track, and while the two, surgeon and patient, were lying beneath the fire-box of the engine.

Medico-legal Society of New York.—Two interesting and important papers were read before the Medico-legal Society, on December 18, 1889, one by Clark Bell, on "Hypnotism;" the other by Charles G. Garrison, Justice of the Supreme Court of New Jersey, on "The Province of Medical Expertism." Mr. Bell held that the medical profession in America does not give hypnotism the attention its importance deserves. Judge Garrison, in speaking of "Medical Expertism," analyzed the legal and medical minds, and showed that they proceeded in radically different ways.

It was the annual meeting of the Society, and the following officers were elected: President, Clark Bell; First Vice-President, Dr. W. W. Godding; Second Vice-President, Albert Bach; Secretary, Emily Kempin; Assistant Secretary, Dr. William L. Baner; Corresponding Secretary, Moritz Ellinger; Treasurer, E. W. Chamberlain; Librarian, Benno Loewy; Assistant Librarian, Dr. G. Bettini de Moise; Curator and Pathologist, Dr. Frederick Peterson; Chemist, Professor H. A. Mott, Jr.; Trustees, W. G. Davies, Dr. Frank H. Ingram, E. W. Chamberlain; Permanent Commission, Judge C. G. Garrison, Professor F. D. Weisse.

The annual banquet of the Society was held in the evening at the Marlborough Hotel.

Sterilized Milk for Sale.—It is stated that some of the druggists of Leipzig have arranged to prepare sterilized milk, after the method of Soxhelt, and dispense it like other articles.

The Polyclinic Medical Society.—The Polyclinic Medical Society gives, under its auspices, a lecture, or holds a meeting of its Therapeutical Section, every Tuesday evening at 8 o'clock, at the College Building, N. W. corner of Broad and Lombard Streets, during the season. The lecture pertains to subjects of a clinical and scientific character, and its monthly meetings will be devoted to the physiological and practical investigation of therapeutic agents. The whole course is free to members of the profession and to medical students. The following lectures and meetings are announced for 1890:

January 7th, Dr. Alexander MacCoy, The Clinical Features of Tuberculosis of the Larynx.

January 14th, Dr. B. F. Baer, Abdominal Surgery.

January 21st, Dr. Thomas G. Morton, Modern Treatment of Club-foot.

January 28th, Meeting of the Therapeutical Section.

February 4th, Dr. Edward P. Davis, Use of the Obstetric Forceps.

February 11th, Dr. John B. Roberts, The Anatomy of Facial Expression.

February 18th, Dr. J. Henry C. Simes, Prostatorrhœa.

February 25th, Meeting of the Therapeutical Section.

March 4th, Dr. R. W. Seiss, Inflammation of the Eustachian Tube.

Homœopathy in New York City.—A contention has arisen between the two wings of the homœopaths in New York City for the control of the hospital on Ward's Island—a city institution. The "liberals," or "renegades," are in possession, while the "ultras" are out, and are trying to get in. The orthodox party appear to be supported by their County Society, while the heretics have the leading journal on their side. The editor of the latter, Dr. Egbert Guernsey, is quoted as saying that since the death of Dr. Bayard there has not been in New York a genuine homœopathic practitioner; and that even his opponents do not hesitate to prescribe drugs regardless of the so-called "science of homœopathy."

The British Pharmacopœia.—The General Medical Council of Great Britain has directed the publication of an *Addendum* to the *Pharmacopœia* of 1885. The *British Medical Journal* of December 7th states that it will contain only remedies of undoubted value which have come into use during the last four years. Dr. Attfield will have the principal responsibility in the work, but will be assisted by Dr. Quain, Sir Dyce Duckworth, and Mr. Carter. The *Addendum* will appear in 1890.

Investigation of Electrical Execution in France.—The medical section of the French Academy of Sciences will investigate the subject of execution by electricity. The inquiry will be aided by the expert electrician, Marcel-Desprez. The visit of the American inventor, Edison, and his presentation before the Academy of his views concerning the painless and instantaneous extinction of life by electricity, have been the incentives to this investigation.

The Fire in the Presbyterian Hospital, New York.—The Presbyterian Hospital of New York City suffered by fire, December 19th, and the patients were safely removed. One very ill woman has since died, whose end may have been hastened by the accident. The fire took place in the north wing of the hospital, which was damaged, according to the estimates of the Trustees, to the extent of about $100,000. It is reported that the elevator would not work, and that no water would flow through the fire-hose with which the wards were provided. If the institution had been more crowded than it was, or if the fire had occurred later in the night, it is extremely probably that great loss of life would have ensued. The moral is that no hospital or public institution should omit to have a regular testing of its fire apparatus and escapes; or when they get out of order to double the night-watch and every other customary precaution.

The Pauper Insane of New York —The New York Charities Aid Association recently held its anniversary meeting. Dr. C. F. Chandler, formerly President of the Health Board, was reëlected presiding officer. The object of the Society this winter will be the reintroduction of the bill to remove the pauper insane from the various county poor-houses and place them in the hospitals to be supported by the State. The Supervisors of the Poor united last year to oppose this measure, and secured its defeat by a small vote. The principal medical societies throughout the State have approved the bill that was defeated last year, or some equivalent measure that will place the insane poor in State hospitals for the insane.

The Hoagland Laboratory.—An announcement by the Trustees of the Hoagland Laboratory, of Brooklyn, has been received, which shows that it is organized for practical laboratory work in bacteriology, physiology, histology, and pathology. A moderate fee will be charged to students who desire to take a full course in some special branch. To the medical profession, however, the advantages of the Laboratory are available almost free of charge, with the exception that when animals are required in any experimentation they must be supplied or paid for by the investigator. All the best foreign journals of laboratory research are in the library.

Growth of Medical Photography.—The uses of photography in medicine are increasing. There are amateur photographers on the staff of a large number of the London hospitals whose prints are in great demand in the surgical wards. The improvements that are now being made in the Royal College of Surgeons include rooms for photography. The President of the College, Mr. Hutchinson, referred to this department in his remarks at the late annual meeting as becoming more and more important in surgical case-reporting.

"Vita Nuova" a Cocaine Preparation.—The "Vita Nuova," of Mrs. Harriet Hubbard Ayer, is said by the *Druggists' Circular* to be a preparation of cocaine, as dangerous as it is pleasant to the taste. The same journal criticises the prominent men and women who have publicly endorsed this much advertised nostrum, when probably, at the most, they have not used more than a single bottle of the stuff. In cases where the use of it has been continued for any length of time, "a testimonial from any such person would be about as valuable as that of a morphine maniac testifying to the beneficial effects of the drug which had enslaved him."

Scarcity of Physicians in Austria.—It is stated that in consequence of the scarcity of medical men in some parts of Austria, an order has been issued by the Minister of Education that men recently qualified who have come from these localities must return to their homes to practise for a certain number of years, unless they are fortunate enough to obtain some Government post elsewhere.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 17 TO DECEMBER 30, 1889.

By direction of the Secretary of War, CHARLES T. ALEXANDER, *Lieutenant-Colonel and Surgeon*, will be relieved from duty as Medical Director Department of the Columbia, on receipt of this order at the headquarters of that Department, and will report in person to the commanding general Division of the Atlantic, for the purpose of preparing for, and becoming familiar with, the duties of Attending Surgeon in New York City. He will also, upon his arrival in New York, assume the duty of Examiner of Recruits in that city. William E. Waters, Major and Surgeon, will take temporary charge of the office of Medical Director Department of the Columbia, upon the relief of Lieutenant-Colonel Alexander, and perform the duties pertaining thereto.—*S. O. 291, A. G. O., Washington*, December 14, 1889.

With the approval of the Secretary of War, the leave of absence granted C. N. B. MACAULEY, *Captain and Assistant Surgeon*, in S. O. 166, Department of the Missouri, November 8th, is extended one month.—Par. 10, *S. O. 294, A. G. O.*, December 18, 1889.

MCCREERY, GEORGE, *Captain and Assistant Surgeon* (Fort Warren, Massachusetts).—Is granted leave of absence for one month, to take effect upon the arrival at that post, for temporary duty, of Samuel Q. Robinson, Captain and Assistant Surgeon.—Par. 6, *S. O. 289, Division of the Atlantic*, December 18, 1889.

ROBINSON, SAMUEL Q., *Captain and Assistant Surgeon* (Fort Hamilton, New York Harbor) —Will proceed, without delay, to Fort Warren, Massachusetts, and report to the post commander for temporary duty.—Par. 5, *S. O. 289, Division of the Atlantic*, December 18, 1889

By direction of the Secretary of War, PAUL R. BROWN, *Captain and Assistant Surgeon*, now at Trinidad, Colorado, will report in person to the surgeon in charge of the Army and Navy General Hospital, Hot Springs, Arkansas, for admission to, and treatment in the Hospital.—Par. 16, *S. O. 296, A. G. O.*, December 20, 1889.

DEWITT, CALVIN, *Major and Surgeon* (Fort Missoula, Montana Territory).—Is granted leave of absence for one month, to take effect not later than January 1, 1890, with permission to apply to Division Headquarters for an extension to include February 27, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING DECEMBER 28, 1889.

STONE, E. P., *Passed Assistant Surgeon.*—Ordered to the "Independence," Mare Island, California.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

OVARIOTOMY AND OTHER CASES.

A Clinical Lecture,
Delivered at the Rush Medical College, Chicago, Ill.

BY CHARLES T. PARKES, M.D.,
PROFESSOR OF SURGERY.

[Reported by A. J. OCHSNER, M.D., Chief of Surgical Clinic.]

OVARIOTOMY.

GENTLEMEN: This case is a German girl, aged nineteen years. She is fairly nourished, though rather slight, and with the abdomen enormously distended. She weighs 120 pounds.

Here we have a case showing the development of a large growth in the abdominal cavity, many examples of which we have lately had before us.

I hope you have become impressed with their grave character, and that you will not do anything with them until you have eliminated, as far as possible, the risks of a mistaken diagnosis.

The tumor is everywhere smooth and even. It is prominent, and does not flatten when the patient lies on her back or in any other position. Vaginal examination shows that there is a hard, unyielding mass extending across the pelvis, and as I feel the surface I notice neither roughness nor irregularities. Placing a hand against one side of the prominent abdomen and tapping it on the opposite side with the finger, I feel fluctuation transmitted to the hand. As this can come only through a fluid, I therefore conclude that it is either free fluid in the abdominal cavity termed ascites, or a large cyst with thin walls.

Careful examination has enabled us to eliminate disease of the liver, heart, and kidneys. There has been no œdema or anasarca present at any time. Hence we exclude ascites and are forced, by exclusion and other facts, to the supposition that this is an ovarian cyst. Moreover, this patient has been tapped five times, as much as thirty pints of fluid being drawn with each tapping; in this case doing no injury to the patient. The first time she was tapped the fluid withdrawn was clear, the next, it was darker, and the last time it had the color of beer or coffee. Ascitic fluid is always clear. One danger attending the tapping of such cysts is the introduction of septic material into the abdominal cavity. This may occur either by the instruments used, or by the fluid from the cyst. There is no excuse for the first, and you can often avoid the harmful effects of the contents of the cyst by being sure that the sac is perfectly empty before removing the trocar.

Proceeding with the operation, you notice that I am very careful in dividing the peritoneum, for I do not know the extent of the attachment of the tumor to the abdominal wall, and do not wish to open the sac.

You can see the blue shining appearance of the sac which is characteristic of such tumors. Just here, near the opening into the peritoneum, I find an adhesion which firmly joins the cyst wall to the peritoneum, and the division of which would have made the opening into the cyst cavity instead of into the abdominal cavity. Having enlarged the opening through the peritoneum to the same size as that in the abdominal walls, exposing the sac freely, I now thrust this large trocar into it, choosing a non-vascular portion for its introduction. The fluid from the cyst flows freely, as you notice, but slowly. It is very thick and is cream-colored, looking like pus. If it proves to be pus, there is no doubt that infection came from the trocar needle used in tapping it. Very likely this resemblance to pus will prove to be dependent upon the presence of a fatty substance found in dermoid cysts.

We must not hurry the emptying of the sac, but give it plenty of time and let it empty slowly. Remember that you should not push the ether while you are emptying the cavity, because the sudden release of pressure may so disturb the circulation that the patient in profound anæsthesia may be unable to rally from its depression.

The diagnosis which I have made that this is a dermoid cyst seems to be correct. You see these adhesions: always strip them up so as to break the vessels as far from the base of the adhesion as possible.

In the separation of the adhesions you may use the finger, the scissors, or the knife. The best way is, if they are soft and recent, to sponge them off; if they are stronger, strip them off with the finger; and if they are broad and thick or vascular, you must include them between two ligatures and cut between these. Here, you see, is a large adhesion of the omentum. These others I do not care much about, for they are not very vascular; but this one is quite vascular, and must be tied. I think I shall be able to show you something interesting in this tumor when we open it, for there was a large, hard, bony mass just across the pelvis, plainly felt during vaginal examination. Nothing but a dermoid tumor has such growths in it.

The cases of ovarian tumors I have shown you thus far this month illustrate the differences in abdominal adhesions. The first case had no adhesions; the second, one or two; and this one has practically any number. In perforating the pedicle you must choose the part with the least vascularity. This can be done very easily with the aid of the eye. You do this so that the point of the needle in passing through will not open a vessel that will subsequently bleed. If you use the clamp, never tie the ligature until the clamp is removed, then there will be no danger of the ligature slipping off. I have the pelvis well open before me, and can see that the opposite ovary is perfectly normal. In closing the abdominal cavity, be sure to bring the surfaces together carefully, but do not draw the stitches too tightly.

The interior of the cyst contains a substance which

feels like bone, and is shaped like a lower jaw. In many of these cases the cyst contains bone or other substances, such as teeth and hair. There is a case reported of a dermoid cyst containing nearly 200 teeth. Now, this is what I felt through the vagina.

In order that the patient shall not suffer from the removal of the great weight of the tumor from the abdomen, we will equalize the pressure in a measure by placing a large bunch of cotton on the abdomen and holding it there by means of a bandage.

[NOTE.—A dissection of the tumor showed a bony mass resembling in size and form the bones of one-half of an adult's face, including a portion of the frontal, the malar, and the superior and inferior maxillary bones, the latter bearing partly developed teeth. Progress of recovery normal. Removed stitches on the eighth day, and wound found united. Patient was out of bed two weeks after the operation, and a week later she was able to walk about.]

THORACIC TUMOR.

I now bring before you a woman, aged twenty-four years, who has a tumor on the right side just below the mamma.

I find that she has a good deal of pain, and that she has become somewhat emaciated. Two years ago she was thrown from a horse and had a rib fractured; since that time this tumor has been growing. I am certain that it is a tumor which had best be let alone. The veins on the surface are very much enlarged, and you have already learned that tumors with this peculiarity are usually not very favorable for operation. The exploring needle, you see, does not tell us anything, so we will make an incision. I make this incision slowly, because I do not know what is under my knife. The tumor slides up and down beneath the chest walls. It is so extremely vascular, and in such a position, that we had better not make any further attempt to remove it.

TALIPES EQUINO-VARUS.

You have seen me operate upon so many of these cases that it is scarcely worth while to describe the operation again. This is a case of talipes varus; the toes turn inward. The tendo Achillis is contracted, and the boy walks on the side of the foot. To-day we shall break down the tarsal bones as much as possible, without breaking through the skin. The deformity has been years in reaching its present condition, and you cannot expect it to be cured at once. We will break it down and put in in a plaster cast in the corrected position, letting it remain for one week. Then we repeat this operation until the normal position of the foot is reached. If you listen, you will hear the bones and ligaments break. I very seldom use the knife in these cases, as you know. Having attained a perfect position of the foot, it is necessary to have the patient wear a cast for about a year in order to secure a permanent transformation of the tarsal bones. The patient can walk in his casts without pain or inconvenience.

The next case is a four-year-old brother of the last patient, and has the same deformity. There is nothing hereditary in the deformity, as both parents and five other brothers are well formed. I operate as in the previous case. This method looks cruel, but in my opinion it is by far the best, cheapest, quickest, and surest way of curing club-foot.

NÆVUS OF FACE.

This little boy, aged two years, has, as you see, a small growth near the superior internal angle of the orbit. It is a nævus. I shall remove it by seizing the growth with the forceps, lift it up and clip it off. A little compression will stop the hemorrhage, and then we will apply an iodoform gauze dressing.

NASAL POLYPI.

In this man's nose I can see a growth forcing its way to the anterior nares. He is unable to breathe through either nostril, and you notice as he speaks his voice has a muffled sound. He is suffering from nasal polypi, which are myxomatous growths developing usually from the mucous membrane covering the turbinated bones and, as they grow, hanging into and occluding the nasal fossa. We will remove them by means of this pair of forceps, which are introduced along the septum of the nose, then opened so as to include the growth, and carried up to its base, which is grasped firmly and the polypus twisted off and withdrawn. This is a case where there are a half dozen nasal polypi hanging in a bunch like grapes to their stem. You see we have removed this large one very easily.

CYST OF THYROID GLAND.

This lady, as you see, has a tumor on the neck in the region of the sterno-cleido-mastoid muscle. It is smooth, even and symmetrical, moving with the larynx when she takes a drink. It is a unilateral cystic growth of the thyroid gland. We will introduce the exploring needle and confirm the diagnosis. I get a chocolate-colored, clear serum. The tumor is partially cystic. We will inject it once a week with a five per cent. solution of carbolic acid. This is a simple method, and often followed by cure.

HYPOSPADIAS.

This little boy, aged six years, has the deformity of hypospadias. In this case it can easily be cured by making a transverse cut, separating the fibres holding the penis down, then sewing the opening longitudinally. It is not necessary in this case to interfere with the urethra.

[NOTE. There was much œdema of the prepuce after the operation and severe pain, but elevating the organ and applying hot boric acid fomentations caused this to subside. The organ has been lengthened 1½ inches, and the downward curve has been corrected.]

OSTEOMYELITIS.

The next patient is a man, aged twenty-seven years, who has a suspicious-looking sinus on the inner side of the thigh just above the knee. It looks very much like the external opening of a sinus leading to a localized osteomyelitis. The patient has chosen rather an unfortunate time for coming, as the sinus is apparently closed. We will open it and examine. I am pretty well satisfied that there is a piece of denuded bone somewhere, but I am unable to find it just now. It is a bad plan to open the sinus with the knife, until you have found the bone. We infer that the disease is moderate in extent, and that this is the reason why the bone is hard to find. The pa-

tient breathes badly. Always pay strict attention to your patient under the influence of an anæsthetic. Let your ears be open to every sound, if your eyes are otherwise engaged. You are responsible for what happens to the patient. I shall open this sinus moderately, hoping a little later to find the track leading to the bone. I may not be able to find the bone to-day. Operating in this location requires great care, because of the large blood-vessels in close proximity to the wound. Patience has its own reward—I have found the denuded bone. I have said that this is a circumscribed disease. There has been no involucrum formed. Now my finger rests in a perfectly smooth cavity, and I have no doubt that the patient will get well. I should have abandoned the case for to-day if I had not reached the surface of the denuded bone. Sometimes when these fragments are small they are hard to find, but you should not give up the search.

You will have noticed that we do not use antiseptic fluids except when we have a septic wound, then we irrigate thoroughly with boric acid or other antiseptic solution. The sinus is curetted and the wound packed with iodoform gauze.

[NOTE. The wound healed rapidly, having been transformed into an aseptic wound. About three weeks after the operation the patient returned to his home, the wound being entirely healed.]

TUMOR OF THE FEMUR.

This young man has been before us twice; his thighs are unequal in size. The right thigh is larger than the left, and symmetrical in its muscular development; the left unevenly enlarged a little above the middle. It is tense and hard to the touch, and the muscular tissue seems wasted. I can make nothing out of it but hypertrophy of the femur. I was at first greatly disposed to believe it to be a malignant trouble. All the appearances pointed to sarcoma, but from the healthy appearance of the man I now think it doubtful. He has been taking iodide of potash and is improving, so I will ask him to go on with the treatment and report again.

EMPYEMA.

This young man received a stab-wound five weeks ago, and was brought to us last night. He is very ill, has great pain and a high temperature, and has lost much flesh. There is some bulging of the chest above and behind the stab-wound, which is between the eighth and ninth ribs, just in front of the axillary line, on the left side. The pus flows freely at every expiration through the wound, which had been closed with a stitch at the time of the injury. The blood from the wound might have filled the cavity of the chest without any further trouble, provided the pus microbe had not been introduced into the cavity. This is simply an abscess, an empyema. If the accumulation of pus had been elsewhere in the body, perhaps it would have been treated without timidity by free incision.

This incision which you now see me make through the tissues and down to and through the sixth intercostal space in the line of the angle of the scapula into the chest cavity should have been made weeks ago.

The pus is now escaping freely, and has a most disagreeable odor. Whenever and wherever you find a large accumulation of pus, open it freely. This cavity will be washed out very thoroughly once or twice with a saturated solution of boric acid, and later with hot water. Two large rubber drainage-tubes are drawn through the cavity and left to protrude through both openings, to insure free drainage. A large iodoform gauze and borated cotton dressing is applied. The cavity is to be irrigated daily with a large quantity of pure, hot water until his temperature approaches normal.

[NOTE. During three days following the operation, the temperature fell from 104° F. to normal, and all septic symptoms subsided. Irrigation was discontinued and the patient continued to convalesce, being nearly well on November 14th.]

ORIGINAL ARTICLES.

A CASE OF INGUINAL COLOTOMY FOR CARCINOMA OF THE RECTUM.

BY H. R. WHARTON, M.D.,

DEMONSTRATOR OF SURGERY IN THE UNIVERSITY OF PENNSYLVANIA; SURGEON TO THE CHILDREN'S HOSPITAL; ASSISTANT SURGEON TO THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

MISS E——, aged forty-eight years, had for some months been troubled with constipation, but had never suffered from pain in the rectum or noticed any discharge of blood or mucus with the stools. I saw her in May, 1889, when she had a more than usually obstinate attack of constipation; and at this time I made an examination of the rectum, but did not discover the presence of any growth or strictures. By the use of laxatives and enemata the constipation was overcome and she had no further trouble until June 10th, when I was called to see her again, and found her suffering from an attack of constipation very similar to the one in which I had seen her before. This attack persisted for some days in spite of treatment, and she soon developed symptoms of obstruction of the bowels; the belly gradually became swollen and tender, and she complained of abdominal pain, but there was no vomiting. I again made a rectal examination, and with the tip of my index-finger I could feel a mass of indurated tissue far up in the rectum, occluding the gut. As the symptoms of obstruction of the bowels were becoming urgent the question of an operation was suggested. Professor Ashhurst kindly saw the patient with me, and after etherizing her I attempted without success to pass a rectal bougie. I now determined to open the descending colon or sigmoid flexure of the colon in the left iliac region, and decided upon the method suggested and practised by Ball, which consists in making an incision in the line of the *linea semilunaris* about three inches in length, with its lower limit just short of Poupart's ligament. This incision was accordingly made, the tissues of the abdominal wall were divided and the parietal peritoneum was exposed and opened, the distended gut presenting itself in the wound; but before this was secured to the edges of the wound the parietal peritoneum was stitched to the skin throughout the wound by fine silk sutures. The presenting gut, which was found to be the upper portion of the sigmoid flexure of the colon, was next drawn well

downward and secured to the edges of the wound by a number of silk sutures, the peritoneal surface of the gut being held in contact with the parietal peritoneum by this means. The distended bowel was next opened by an incision about an inch in length, when a large quantity of semi-fluid fæces and flatus escaped. After the wound had been cleansed of fæces the edges of the intestinal wound were stitched to the skin by a few silk sutures. The wound was next freely dusted with iodoform; a few layers of carbolized gauze were then applied, and a pad of bichloride cotton was placed over this, and the dressing was held in position by an abdominal binder. The patient had a number of copious passages during the next twenty-four hours, and was entirely relieved of her pain and discomfort, and presented no unfavorable symptoms. At the end of the eighth day the sutures were removed and the adhesion of the gut to the abdominal wound seemed perfectly firm. At the end of two weeks the patient was allowed to be out of her bed, and in a short time was able to go about the house and even out of doors. She had a free fæcal movement each morning, and was not often disturbed again during the next twenty-four hours by the escape of fæcal matter, but suffered annoyance from the escape of flatus. After the first week she passed some thin fæcal matter mixed with blood from the anus, and it was found advisable to use an enema of a weak solution of permanganate of potassium occasionally. I saw her frequently, and found her condition as described above. A careful examination of the artificial anus showed no tendency to prolapse of the bowel. The patient continued in a comfortable condition until August 17th—about two weeks after the operation—when she noticed that no fæcal matter escaped from the artificial anus. I saw her upon the following day, and found that the belly was slightly swollen and that she complained of pain in the right iliac region. I introduced my finger into the artificial anus to ascertain if the bowel was occluded by a mass of inspissated fæcal matter, but I found it perfectly clear as far as I could explore it with the finger and a soft catheter. I was called to see the patient on the evening of August 18th, and found her in collapse, and she died in this condition early on the morning of August 19th.

Examination of the region of operation after death showed that the adhesion of the colon to the abdominal wound was firm, the lower portion of the sigmoid flexure, occupied by a carcinomatous growth, was found displaced to the right side of the body, occupying almost the entire right iliac region, and the growth and a number of coils of the small intestine were matted together. At one point the small intestine was opened by ulceration, permitting the escape of fæcal matter into the abdominal cavity.

Remarks.—In the above case the result of the operation was most satisfactory, both as regards the immediate relief of the symptoms of obstruction of the bowel, and the comfort of the patient, until a new point of obstruction developed by reason of the extension of the growth, which was followed by perforating ulceration of the intestine and a rapidly fatal issue.

Carcinoma of the rectum sooner or later, in the vast majority of cases, leads to stricture of that organ and to the development of symptoms of intestinal obstruction. If, by reason of the situation or extent of the growth, the case is unsuitable for the operation of excision of the rectum or for linear rectotomy, the operative treatment of the affection consists in the performance of either lumbar or inguinal colotomy.

Colotomy relieves the symptoms of obstruction of the bowels, and generally keeps the patient in a comfortable condition until death results from other causes. The influence of the operation in retarding the growth of the disease in the rectum is a question upon which different observers are not fully agreed; some surgeons of large experience in this operation are decidedly of the opinion that following the operation there is a marked retardation of the increase of the rectal growth.

The operation is also in many cases delayed too long; it should be performed before the obstructive symptoms become too urgent, as the immediate risk of the operative procedure is diminished by operating at this time, and there is then an opportunity to delay the opening of the bowel for twenty-four or forty-eight hours, until it has had time to acquire firm adhesion to the abdominal walls, thereby diminishing the chance of fæcal extravasation.

Inguinal or iliac colotomy is the operation which at the present time meets with most favor, and it has the advantage over lumbar colotomy that, by its employment, the bowel is more easily found and the resulting artificial anus is in such a position that the patient cares for himself more readily. In the inguinal operation, moreover, the surgeon can more readily close the lower portion of the bowel if he considers it better to make the artificial anus a terminus instead of a lateral outlet to the bowel.

Prolapse of the bowel is said to be more common after inguinal colotomy than after the lumbar operation, and as this is a condition which causes the patient much discomfort, it should be guarded against at the time of operation by drawing the upper portion of the loop as far down as possible before it is fixed to the abdominal wound.

This is, I think, more important where the operation is done in a case of fibrous stricture of the rectum where the patient's expectation of life is good, than where the procedure is adopted in a far advanced case of malignant disease where colotomy can only be considered at least a palliative procedure.

The tendency to prolapse of the bowel in inguinal colotomy depends directly upon the variable length of the sigmoid mesocolon.

Mr. H. Allingham, to overcome the tendency to

prolapse of the bowel through the artificial anus, recommends the drawing out through the wound of both the upper and lower portion of the bowel until the mesocolon becomes tense; he then passes sutures through the mesocolon and the muscular and serous coats of the bowel to prevent its slipping back. He next applies a clamp with spikes to hold the bowel in this position, which is allowed to remain from twelve to seventy-two hours, according to the urgency of the case; the gut above the clamp is cut off, and if when the clamp is loosened there is no bleeding it is removed permanently. The amount of intestine cut off in some of Mr. Allingham's cases has been as much as twelve inches. I think the incision recommended by Ball, which was the one employed in the previously reported case, is the best one to make use of in inguinal or iliac colotomy. It is an incision about four inches long in the line of the left *linea semilunaris*, which exposes the sigmoid flexure freely and is made at a point where the parietes are thin and no vessels of importance are injured. Whether it is advisable to make the artificial anus a terminus of the gut, by closing the lower portion, will depend upon the conditions which are presented when the abdominal cavity is opened and the gut exposed; if the rectal growth is high up, so that the bowel can be emptied, and if it does not contain much discharge from the growth itself, it is well to empty it and close it after securing the upper extremity of the gut to the abdominal wound. In other cases where there is difficulty in emptying the lower portion of the gut, or where there is free discharge from the growth into the gut, it is better to be satisfied to have the artificial anus act as a lateral outlet to the bowel, as the lower portion of the gut can then be washed out out with some disinfectant solution, if required.

It not infrequently happens, even in cases where the obstruction of the bowels was absolute before colotomy was performed, that the rectum below the growth becomes distended with thin fecal matter and discharge from the growth; this is generally noticed a few days after the operation, and it causes the patient much discomfort and gives rise to a very offensive odor; this condition is best overcome by using, daily, a rectal injection of a weak solution of permanganate of potassium as long as any discomfort is experienced.

HYSTERICAL BLINDNESS OF TEN YEARS' DURATION IN A HEALTHY MALE SUBJECT.[1]

BY GEORGE C. HARLAN, M.D.,
OF PHILADELPHIA.

SIXTEEN years ago I reported several cases of hysterical amblyopia under the head of "Simulated Amaurosis" (*American Journal of the Medical Sciences*, October, 1873), and since then have chanced to meet with a number of cases, some of which have been published from to time. The subject has been discussed so frequently of late years in journals and lectures and works upon the nervous system, that the excuse for reporting such cases as a warning to be on the lookout for their possible occurrence in female patients no longer exists. The same cannot yet be said where male subjects are concerned, and perhaps it is still in order to remind the profession that this strange psychical whim, or whatever it is, is not altogether confined to the more irresponsible nervous organization of the gentler sex. In one of my first cases the patient was a male, and the following is the report of his case:

A rather delicate-looking boy, æt. eleven years, was represented to have become blind in the right eye about eighteen months before. After the disease had resisted the skill of the family physician for some months, the patient's father was recommended to "try electricity," and took him to a "professor" of that science. The result of one application was an entire restoration of vision. The cure lasted, however, only for a few weeks, when the remedy was resorted to again, with the same result. After this history had repeated itself a number of times, the father, as a measure of economy, invested in an apparatus of his own, and wound up his son's vision as often as it ran down.

When brought to the Wills Hospital, the boy asserted that the eye was not conscious of the ophthalmoscopic examination, which, however, revealed nothing to account for the loss of sight. When a prism was placed before the left eye he admitted seeing two images of the gas-jet, which could easily be distinguished by a colored glass or made to unite by a corrective squint when the base of the prism was held outward. He was required to read with the prism still before the eye, and while he was disconcerted and thrown off his guard by being urged to read rapidly, a fold of paper was slipped in front of the left eye and he continued to read with the right. The father was quite sure that there was no motive for the deception. The fact that the boy's mother was blind in the right eye was a singular coincidence, and, perhaps, may have had a psychological bearing in the case.

About the same time I met with the report of a case by Galezowski, of Paris, in which the patient was also a boy, eleven years of age. Galezowski considered it a plain case of malingering; and in my own report I spoke of the pretended blindness as a deception. What I have since seen in other cases convinces me that we both may have been wrong, and raises a strong doubt in my mind whether either of these patients could have seen by conscious effort with the eye supposed to be blind.

No other instances of this affection occurring in males have come to my knowledge until Dr. William A. Moore reported three cases at the last meeting

[1] Read before the American Ophthalmological Society.

of the American Ophthalmological Society, and Dr. Edward Jackson referred to one that had recently occurred in his practice. Another has since been reported (*New York Medical Journal*, February 9, 1889) by Dr. Marlow. The following case presents several points of interest other than the sex of the patient:

A tall, well-developed man, twenty-two years of age, a clerk in a railroad office, living some distance from Philadelphia, came to me in March last with the following history: Ten years ago, while walking in the street, he was struck on the right eye with a stone thrown by a boy. Considerable pain and inflammation followed the injury, and the sight of the eye was lost. He was for several months under the care of a well-known ophthalmic surgeon, and finally discharged as incurable from supposed paralysis of the optic nerve. His eyes had since been a constant source of anxiety to his parents, and had proved a serious interruption to his education. He had recently suffered considerable eye-strain and frontal headache after work at his desk, which had occasioned him much uneasiness, particularly as his family physician had assured him that it might be necessary to have the blind eye removed to save the other one. Under these circumstances he came to Philadelphia for special treatment, quite ready to submit to enucleation if it should be advised.

In the left eye V. $= \frac{20}{XX}$, and no manifest hypermetropia. Ophthalmoscopic appearances normal. In the right eye, he stated that there was no light-perception—that he was not conscious of the light-reflection from the ophthalmoscopic mirror; but the appearance of the eye was natural, the pupil responded to light, and the ophthalmoscope showed absolutely nothing abnormal but a low degree of hypermetropia. His appearance and manner were so utterly at variance with any suggestion of hysteria, or any kind of nervous derangement, that the suspicion of it did not at first occur to me. At the second visit, with both eyes fully under the effect of homatropine, ophthalmoscopic examination gave the same negative result as before. The mydriatic revealed a latent hypermetropia of 1.25 in the left eye, which had been the cause of the asthenopic symptoms. As a last resort, a prism with base down was held before the left eye, and, to my surprise, double images of a gas-jet were at once admitted. This, of course, proved that both eyes saw; how well the right could see was easily shown by a simple test which has never yet failed me in similar cases. A + 1.25 glass, which merely corrected the error of refraction, was placed before the right eye, and before the left a + 4 D., which excluded that eye from distant vision without the knowledge of the patient, and he was directed to read the test letters at twenty feet. He read No. 25 without hesitation—of course, with the blind eye. I then closed the left eye and called his attention to what he was doing. His surprise was equalled by his joy at the discovery, and both were evidently genuine. There was no suspicion in my mind of a conscious deception on his part; in fact, he had been ready to seal his good faith by the sacrifice of his eye.

Interesting points in this case are the long continuance of this imaginary disease and the entire absence of any other symptoms of irregular nervous action. After remaining firm in the belief of his blindness for ten years, there is no reason why he might not have carried this imaginary burden through the remainder of his life. The patient himself considered his general health to be perfect, and his uncle, a well known medical practitioner, assured me that he had not only always been free from any other suggestion of hysteria, but that he knew of no young man in whom he would be more surprised to find symptoms of nervous derangement.

The behavior of the pupil should have excited suspicion of simulation at once, as prompt pupillary reflex in a blind eye may be considered a physiological paradox. My excuse for not having entertained this suspicion at first is the apparent absurdity of that view of the case when the history and present condition of the patient were considered. That the converse does not always hold—that a perfectly immovable pupil is not positive proof of something more than hysteria—was shown by a typical case of hysteria that I reported to the Ophthalmological Society in 1884, in which a widely dilated and fixed pupil was one of the symptoms promptly relieved by the application of a wooden imitation of a magnet.

THE POST-MORTEM IMBIBITION OF POISONS IN ITS MEDICO-LEGAL BEARINGS.[1]

By JOHN J. REESE, M.D.,

LATE PRESIDENT OF THE MEDICAL JURISPRUDENCE SOCIETY OF PHILADELPHIA, AND PROFESSOR OF MEDICAL JURISPRUDENCE AND TOXICOLOGY IN THE UNIVERSITY OF PENNSYLVANIA, ETC.

The phrase—*post-mortem imbibition of poisons*—literally signifies the imbibition of poisons into an animal body after death. To the toxicologist, however, it has a more distinct, specific meaning—namely, the infiltration into the different organs and tissues of the body of a poison which has been introduced after death either into the stomach, the rectum, the abdominal or the thoracic cavities, and which has subsequently penetrated by transfusion into the adjacent viscera.

The whole scientific interest and importance of this subject centre in the fact so essential to the toxicologist—that in his search for a poison in a dead body, in a criminal case, the grand object of the analyst is not merely to discover this poison in the stomach (since there is always the *possibility*, at

[1] A paper read before the Medical Jurisprudence Society, of Philadelphia, by special request at the stated meeting Nov. 12, 1889.

least, of its having been introduced here after death), but rather to detect its presence in the various organs and tissues of the body, as the liver, kidneys, spleen, heart, lungs, brain, spinal cord, and even the muscles and bones, into which it had been carried and deposited by the circulation during life, and where its remains may often be discovered a long time after death.

Now, the detection of this *absorbed* poison—as it is rightfully named—in any of the organs of a dead body has hitherto been universally regarded as the most positive and satisfactory proof that the poison had been taken during life, and that it was undoubtedly the real cause of the death, in the absence of all other obvious causes, revealed by the post-mortem examination. Certainly, it would seem, there could be no other legitimate conclusion. But it will be at once apparent that if it can be shown that by introducing a poisonous solution into the stomach, rectum, abdominal or thoracic cavities, or bloodvessels, *after* death, this solution will pass through the walls of these cavities, by the well-known physical law of osmosis, or transfusion, and will gradually but surely penetrate into the adjacent viscera—first into the nearest ones, and subsequently into those more remote, so as to be discovered in them by chemical analysis; then I submit that a most serious and vital difficulty might present itself, fraught with no little danger, namely, the risk of confounding or mistaking the one condition for the other, in a case of alleged criminal poisoning, where the issues of life and death are at stake, and where the evidence for conviction might be dependent chiefly or solely on the chemical analysis. For, as is evident, there is absolutely nothing in chemistry alone to distinguish between them; the same tests must be applied to both, and they must yield the same results.

Those persons who have given no special attention to this subject may be surprised to learn that such a question should ever be raised in a criminal trial for poisoning; but cases not a few have occurred, and their number is increasing, where the whole question of the guilt or innocence of the prisoner may hinge simply upon this very point—whether the poison that has been discovered in the organs of the deceased may not possibly have been first introduced into that body after death, for a wicked and fraudulent purpose—either to create a false impression that the deceased had actually been poisoned, although his death had been correctly attributed to other and natural causes, or else in a case of actual criminal poisoning, where the guilty criminal has sought to cover up his work, and escape detection, by injecting the same poison into the body of his dead victim (for example, a solution of arsenic, or of corrosive sublimate) under the specious guise of embalming or preserving the body; but, at the same time, armed with the guilty knowledge that the poisonous liquid thus introduced would speedily be diffused through the different organs of the body, and would thus render abortive the subsequent attempts of the toxicologist to prove that the death had been caused by poison. Cases of this latter character have more than once been brought to my notice.

The bare fact that a dead body may imbibe a poison was first clearly demonstrated by Orfila, more than sixty years ago, by experiments made first on the bodies of the lower animals, and then upon the human body. He found that when a mineral solution was injected into the stomach or rectum after death, it was speedily diffused throughout the various viscera; the completeness of the diffusion and the number of the organs affected being always in proportion to the strength of the poisonous solution, and the length of the interval between the injection and the examination of the body. This is precisely what we might have expected.

Orfila also distinctly exposed the fallacy of the prevalent popular idea that a dead human body might possibly absorb the poison if buried for a long time in an arsenical soil. Now, as this is a question of some medico-legal importance, I will dwell upon it for a moment. It is well known that the soil of certain cemeteries contains traces of arsenic—more frequently in Europe than in this country. Hence it occasionally happens in a trial for alledged arsenical poisoning, where the evidence against the accused is chiefly of a chemical character, that the counsel for the prisoner, driven to extremities, will take refuge in the now exploded idea that the arsenic found in the body of the deceased was really due to absorption from the soil of the cemetery, more especially if the body had been interred for many years, so as to have given time for the coffin to fall to pieces, and the remains to come into actual contact with the poisoned soil.

But, as I have just observed, Orfila distinctly proved the fallacy of this notion. He showed by experiments that imbibition from an arsenical soil can never happen, and for the very sufficient reason that the arsenic existing in the soil of cemeteries is never in a soluble state, and consequently could never be absorbed. This opinion of Orfila is now universally adopted by toxicologists; and I believe that no well-instructed criminal lawyer of the present day would hazard his reputation by urging such a plea before a court and jury.

The experiments of Orfila already alluded to, to prove the *fact* of the imbibition of poison after death, have since been frequently repeated by other investigators, among whom is myself. Some years ago I instituted a series of experiments at the University of Pennsylvania, or rather I supervised those

made at my suggestion by Dr. George McCracken, of this city, a member of my class. My paper, containing the results of these experiments, was read before the College of Physicians of Philadelphia, and was published in its *Transactions*, 1877.

The animals whose bodies were employed were cats and dogs. The poisons used were solutions of arsenious acid, corrosive sublimate, and tartar emetic. These were injected through a tube, into the stomach, and the bodies were then buried in the earth for periods varying from three to seven weeks. On subsequent examination the clearest possible proofs of the diffusion of the poisons into adjacent viscera were afforded; they were detected in the lungs, diaphragm, spleen, kidney, heart, and urinary bladder, by chemical analysis; and also rendered visible to the eye by the deposit of characteristic colored spots of the respective sulphides in the peritoneum and mesentery—*yellow* in the case of arsenic, *orange* in that of antimony, and *black* in that of mercury. These experiments also confirmed another fact mentioned by Orfila, namely, that this post-mortem imbibition is progressive, depending upon the length of time elapsing between the injection of the poison and the examination of the body.

I regret to say that at this time no examination was made by me of the brain and spinal cord; because I did not, at that date, believe that a poison thus imbedded could possibly pass through so many intervening tissues, and at last penetrate the thick bony casements enclosing the brain and spinal marrow. Moreover, at that time no experiments had been made to ascertain this fact; and I then even ventured to express the opinion that such a result could hardly be expected; so that the discovery of a poison in the brain or spinal cord after death might be regarded as pretty sure proof of ante-mortem poisoning, whilst its detection in any of the other organs could not be received as such incontrovertible evidence, inasmuch as they might possibly have become contaminated by a post-mortem imbibition.

But certain experiments conducted subsequently to my own, especially those by Dr. George B. Miller, of this city, another member of my University class, and by Professor V. C. Vaughan, of the University of Michigan, and others, seem very positively to establish the fact that *arsenic* certainly (and other poisons presumably) does really reach both the brain and spinal cord after previous injection into the stomach of a dead animal. I have as yet no data to prove that this result would follow the injection of the poison into the rectum, or into the abdomen or thorax, but I have very little doubt that such would be the case.

Thus it has happened that this lately ascertained fact, although deeply interesting from a scientific point of view, proves to be unfortunate in another respect, inasmuch as it destroys completely what otherwise would have been a most valuable and trusty means of diagnosis.

We all know that it is much more difficult for the toxicologist to detect the poisonous alkaloids—strychnine, morphine, nicotine, etc.—in the organs after death, in a case of genuine ante-mortem poisoning, than it is to discover the mineral poisons, arsenic, mercury, antimony, lead, etc. Of course, the difficulty would be proportionately increased in the attempt to detect these alkaloids in the viscera when injected into the body post-mortem. So far as I am aware, no experiments in this line have been made, or, at least, have not yet been published, until those recently performed by my friend, Dr. Miller, whom I have already quoted. He has within the past few years made a series of investigations to test this fact, more particularly with the alkaloid strychnine, taking it as a type of the alkaloids. He has kindly exhibited to me the results of his experiments, which were performed upon the dead bodies of rabbits. A strong solution of strychnine in water (ten grains to one fluid-ounce) was carefully injected into the stomach by means of a tube passing through an incision made in the œsophagus, this mode of injecting being adopted in order to avoid any possibility of the poison regurgitating from the syringe through the posterior nares, and thence through the sphenoid and ethmoid cells directly into the brain. The animals were examined at various periods after interment, varying from twelve days to several weeks; and, as the result, Dr. Miller feels perfectly sure (and I can see no reason to doubt the accuracy of his results) that he has detected strychnine imbibed post-mortem in the *liver*, *spinal cord*, and the *urine* remaining in the bladder. In the brain, however, he has not, thus far, succeeded in finding it.

I think, then, that we may regard it as an established fact that *all* poisons—organic as well as mineral—at least all those susceptible of solution, do undergo the process of imbibition or transfusion into the various organs and tissues of a dead body; and, further, that in every criminal trial for poisoning this important fact should always be kept in view for the benefit of the accused, and that in every toxicological examination of a dead body the possibility of the post-mortem transfusion should never be forgotten.

We are now naturally led to consider the important question whether there is any means by which, in the case of death from alleged criminal poisoning, we can positively discriminate between the poison administered before death and that which may have been injected into the body designedly after death. This is, of course, a question of momentous importance. Several cases have come to my knowledge where the whole question of the guilt or innocence

of the accused hinged on this very point. For instance, an old man has died from some ordinary disease, but with no symptoms leading to the suspicion of poisoning. Previous to his death he had made a will, bequeathing the bulk of his property to his housekeeper, whom he had lately married, and leaving his children comparatively penniless. Now, these disappointed heirs restrained by no moral principle, might determine to thwart this unnatural act of their father, and to effect their wicked purpose they hesitate not to hatch a most diabolical scheme, viz., to charge the woman with the horrid crime of poisoning her husband for the purpose of obtaining his money. Armed with the fatal knowledge of the post-mortem imbibition of poisons, they secretly gain access to the buried body of their parent, and with no great difficulty succeed in introducing a solution of arsenic into the stomach, and, after quietly waiting for a few weeks or months, they begin to whisper the suspicion that there was a mistake as to the cause of the old man's death, and that there was a strong suspicion that he had been poisoned. This allegation would be rendered the stronger if any of the symptoms at the time of his death had happened to resemble those of an irritant poison. Very soon the tongues of gossip and slander would spread the flame of suspicion throughout the community, until it reached the ears of justice, when, forthwith, the exhumation of the body and an judicial examination follow. As the result of the latter, the presence of the dreaded arsenic is discovered in the different viscera of the body. And what follows? Sad to relate, the arrest and possible conviction of a perfectly innocent woman, around whom has been insidiously woven a net of suspicious "circumstances," through the meshes of which it seems almost impossible for her to escape. This is no mere fancy sketch; its counterpart is believed to have occurred more than once.

But take another illustration, of an altogether different nature, and one much more likely to occur. A husband, prompted by some base motive, determines to get rid of his wife by poison. It is administered to her secretly, and in small doses, so as gradually but surely to accomplish the desired end. The physician who may be called in, as well as the attendants upon the sick woman, may be entirely deceived as to the real condition of things, and the poor victim is treated for some supposed disease, until death ensues. Immediately afterward the designing husband, with a full knowledge of the consequences, and under the specious pretence of embalming the body of his wife, injects into the abdomen a strong arsenical solution—such as is often used by undertakers. Or, perhaps, he may even employ a physician or an undertaker to perform the job. The body is then duly buried, and the guilty husband hopes that his villany has been covered up; for, even if subsequently suspicion should be excited, and the wife's body should be disinterred and examined for poison, its detection in the different organs and viscera by the toxicologist might, as we have seen, be readily ascribed to its post-mortem imbibition, resulting from the embalming liquid. Again the important question presents itself—how are we to discriminate in such awfully intricate cases, in which the innocent may be made to suffer and the guilty may escape free? I answer, not by chemistry merely, since the results of a chemical analysis must necessarily be the same in both cases.

There are some considerations, however, which may possibly tend to throw light upon this confessedly intricate subject. As now understood, in every case of death from actual poison a careful toxicological examination of the body will usually reveal the remains of the poison which has been absorbed and retained by the different viscera, more especially by the liver and kidneys. In any such case, it is noted that the interior of the organ contains quite as much of the poison as the exterior, because it has been deposited there by the capillary bloodvessels during life; whereas, in a case where the organ has been contaminated by a post-mortem imbibition of a poison, the exterior of the organ should indicate a larger amount than the interior, and for a reason obvious on a moment's consideration. This may be regarded as one factor of the diagnosis, although perhaps not a very strong one.

Another circumstance worthy of greater consideration, although I believe it has never yet been thoroughly worked out, is that there is, probably, a histological and pathological change wrought in the tissues and organs impregnated with certain poisons, and visible only under the microscope. This alteration would be likely to occur only as the result of absorption of the poison into the circulation during life, and not from mere physical transudation after death. It is now well known that in cases of slow poisoning by arsenic, lead, and other metals certain neurotic symptoms are developed, accompanied by well-marked pathological lesions in the great nerve centres. In an address by Dr. Formad, of Philadelphia, before the International Congress of Medical Jurisprudence, lately convened in New York, upon this very topic, the opinion was expressed that there is always a very decided histological and pathological alteration in the mucous membrane of the stomach (he does not mention any other organ) produced by true arsenical poisoning, and differing from that caused by corrosive sublimate. He further asserts that "poisons introduced into the dead body do not induce any histological changes in the tissues whatever." This I believe to be the true direction

in which to seek for the solution of this vexed question—the histological and pathological changes wrought in the tissues and organs by an ante-mortem poison; indeed, it may be regarded as the crucial diagnostic test, so far as it goes. We have, as yet, no evidence whatever of its application to the organic poisons.

But here I would guard against an error held by some, that any mere pathological alteration discovered in a stomach after death is sufficient, of itself, to warrant the conclusion of death by poison, and this for the simple but sufficient reason that these same pathological changes are often produced by disease. I admit there may be a very few exceptions to this view, as, for instance, in poisoning by the strong mineral acids or alkalies; but with these exceptions, I should consider it extremely hazardous, in a capital case, to found an opinion as to death by poison *solely* on the post-mortem appearances of the stomach.

A third factor in the diagnosis is the examination of the urine *before* death in a suspected case. This examination ought never to be neglected by the attending physician. An analysis of the urine after death—especially long after death—is much less satisfactory, since it has been shown that a poison may penetrate from the stomach into the urinary bladder by a post-mortem imbibition, and so contaminate the urine.

After all, we must be compelled in such cases to fall back upon what are termed the "circumstances" of the case. One of the strongest of these circumstances is the symptoms manifested by the deceased before death. As is well known, most of the violent, irritant poisons, when taken in fatal doses, are accompanied by well-marked symptoms, which, to an experienced observer, are very suggestive. But it should be remembered, they are *merely suggestive:* they do not convey absolute *proof* by any means, because these very same symptoms are sometimes simulated by disease. Thus I have, more than once, found large quantities of arsenic in the bodies of persons who were supposed to have died from cholera morbus, and who had been treated by physicians for this disease, and the cause of their deaths so certified by the physicians, so closely do the symptoms in both conditions resemble each other. But if the poison has been administered in small doses at intervals, then the symptoms are altogether different, and they may very readily be mistaken for those of some insidious disease.

And, finally, under this head, I should not omit to allude to those "circumstances" which, when they do occur, constitute a most important link in the chain of evidence: such as the existence of a strong impelling motive to the deed, on the part of the accused, or of some interest he may have had in the death of his victim—as, for example, the obtaining of a life-insurance claim. Likewise, the proofs of the purchase and actual possession by the accused of the very poison discovered in the body of the deceased; and, possibly, also the discovery of some implements belonging to the accused, such as, it might even happen to be, the very syringe and tube employed by him to inject the poisonous liquid after death, with enough of the remains of this liquid still adherent to the implements to be recognized by the toxicologist.

All these and many other such "circumstances" constitute invaluable material which an astute and judicious counsel will not fail to work up into most important testimony, either for or against the prisoner.

From what I have said, I think all must be impressed with the importance of the subject of the *post-mortem imbibition of poisons*—especially to the toxicologist and the legal physician. My own mind has been especially directed to it in its relation to the unauthorized and indiscriminate use of poisonous mineral liquids, injected into the bodies of the dead, for the purpose of embalming or preserving these bodies, by several cases lately brought to my notice which occurred in neighboring States, and in which the ends of justice were completely foiled by this pernicious practice. In two of these cases the poisonous compound was injected soon after death into the abdominal cavity by an undertaker, apparently without any authority, or orders, but solely to follow out his own ideas, or to carry out his usual custom. Now, in both these cases, there was a strong suspicion of death by poisoning. I would ask, does not an undertaker by such unauthorized action, although perfectly innocent of any guilty connivance, render himself liable to a very strong suspicion of such guilty complicity? And might not even an innocent physician, performing this operation in kind compliance with the request of the real poisoner and, of course, without any suspicion of the true cause of death, thus subject himself to the terrible consequences of being accessory to the crime? The third case which was referred to me—strange to say, from the same State—was that of the wife of a clergyman, who had died under strong suspicions of poisoning by arsenic. The husband, very soon after the death, caused an arsenical solution to be injected into his wife's body, ostensibly with a view of preserving it, but doubtless with the intention of thwarting the ends of justice by thus rendering the proof of poisoning impossible. The case was rendered stronger by the fact that this clerical Bluebeard had previously lost several wives, two of whom under precisely similar circumstances. The case, I learn, is still held under advisement, as the husband was not as yet under arrest, in consequence of certain family reasons.

Now, with a full knowledge of the above cases,

and impressed with the danger and risk incurred by the community by this indiscriminate and unauthorized injection of dead bodies by undertakers and others, I some weeks ago sent a communication to our Board of Health, drawing their attention to the danger of allowing such indiscriminate embalming of the dead without proper authority, remarking, however, that I was not aware of any such cases occurring in this city, but that I knew of them elsewhere. My communication was intended to be merely precautionary: to call attention to an evil that did exist elsewhere, and which it was desirable to prevent getting a foothold here. I suggested the passage of an ordinance forbidding any undertaker, physician, or other person whatever, injecting any poisonous or embalming fluid into a dead human body, without proper authority, except for the preservation of subjects for dissection in medical colleges. I was glad to learn from a somewhat vigorous protest from one of our undertakers that such an indiscriminate use of embalming fluids was *not* common in this city. Still, the passage of such an ordinance might certainly be productive of good, since I have the most positive evidence that the practice alluded to is very common in other parts of our country.

THE CLIMATIC TREATMENT OF GASTRO-INTESTINAL DISEASE IN CHILDREN.

BY BOARDMAN REED, M.D.,
OF ATLANTIC CITY, N. J.

CLIMATIC treatment can at present be carried out only by transporting the patient to some locality having a different climate. The time may come when a change of air (which is not all there is, however, in a change of climate) may be obtained by conveying to sick-rooms in the cities various qualities of air through pipes from the seashore, country, or mountains, as coal-oil is now sent to market. The physician of that future golden age may then prescribe for his patients a special kind of air as readily as water from a certain spring, and the nurse can have it turned on just as she now does gas, water from the spigot, or hot air from the register.

Why does a change of air often effect such striking remedial results? The question has never been satisfactorily answered.

When a sick child is removed from the hot, stifling, and germ-polluted air of a great city in summer to any comparatively cool and healthful place, there are reasons enough why marked improvement results. But when a weakly infant resident in the most salubrious mountain home contracts diarrhœa from improper feeding or imprudent exposure to extremes of heat or cold, and the disease runs a slow course, a change to the seashore will usually have a like beneficial effect. Then, when the same thing happens to a child resident at the shore, a change to the moutains may be equally helpful.

We can only infer that in such cases the breathing of a different air acts as a stimulant to the vital processes. The probability is that there are ingredients peculiar to the atmosphere of every locality that have a tonic effect at first, until, like too long a course of quinine or other roborant drug, they cease to stimulate. Then, upon taking the patient to another climate, other tonic ingredients are inspired, with at first an invigorating and restorative effect as before.

Some such varying substances there must be in the air of every region, whether they are gaseous elements unrecognized by the chemist, or only coarser material particles held in suspension, as certain amounts of saline constituents are known to be held in suspension in sea air.

When recently requested to write a paper on the climatic treatment of cholera infantum, I objected that the subject was too restricted. Another reason for desiring to enlarge its scope to "gastro-intestinal disease in children" was that at the seaside resorts where most of my clinical experience has been acquired, cholera infantum is a rare malady, and, that therefore, I am less familiar with that affection than with most others that afflict babyhood.

Its later stages and its results I see very often, since it is exceedingly common for infants to be sent to the seashore as soon as the violence of the attack is over, whether the after-condition is a subacute or chronic entero-colitis, or one of slow convalescence with great debility.

But no case of genuine cholera infantum has occurred in my practice at Atlantic City for at least four years. It may be only a coincidence that for about the same period of time the town has had an excellent water supply, and a system of effective underground sewerage in full operation. During the preceding years, when its sanitary condition was less perfect, cholera infantum, though very infrequent, was met with by me occasionally.

Evidently the best treatment for the graver forms of "summer-complaint" is the preventive one, and the best method of prevention is to take teething infants away from the large cities before the hot season begins. One of the recognized authorities on this subject[1] says: "People with means avoid the dangers of summer diarrhœa by taking their children to the country, seashore or mountains, where the air is uncontaminated, the heat less intense, and the milk pure."

When such preventive treatment has been neglected and one of the dreaded summer maladies has attacked a child, change to a more salubrious

[1] Starr. Diseases of the Digestive Organs in Children page 181.

locality is still usually possible. In the earlier stages of cholera infantum removal to a distance is not often practicable; but later on, after the equilibrium of the circulation has been somewhat restored, no remedy is more efficient for the resulting dangerous prostration—whether accompanied by diarrhœa or not—than a transfer to some cooler and purer atmosphere. The most beneficial change in such cases is either to the mountains or seashore. Either answers well in the majority of cases, and the relative proximity or convenience of access often, properly enough, decides the choice. No complicating conditions could contra-indicate the seashore, except advanced phthisis, but infants with organic heart disease or seriously enfeebled circulation should not be taken to very high altitudes.

The more stubborn subacute and chronic intestinal fluxes, which in infancy may generally be classed pathologically under the term *entero-colitis*, are the most important of the affections now under discussion. They cause every summer a frightful mortality. Fortunately change of climate may not only be resorted to in advance with a reasonable certainty of preventing them, but may be employed also as the most efficacious means of cure in attacks that have resisted treatment at home.

When children wasted and debilitated to the last degree with diarrhœa are removed to a favorable locality by the sea, such as Atlantic City, concerning which I can speak definitely from a long personal experience, the result is usually a prompt and surprising improvement, which in some cases seems well-nigh miraculous.

The pale, languid, and emaciated little sufferers brighten up with the first whiff of the salt air. Peevish restlessness and wakefulness soon give place to quiescence and sound refreshing sleep. The flagging pulse rallies and becomes stronger. The appetite improves; food is better retained and better digested. In consequence there is a tendency to an improvement in the character and diminution in the number of the evacuations. The hollow eyes assume a more natural expression, and the shrivelled limbs grow plumper.

All this may, and often does, result from the stimulating effect of the change of air alone. More frequently, however, such patients require skilful medical attention as well as the best of nursing for the first few days at least.

This is not the place to discuss methods of drug treatment, and, therefore, I shall not go into that matter further than to mention *en passant* that small doses of creasote, carbolic acid, or mercurials, minute doses of arsenic or podophyllin, and moderate doses of bismuth or naphthalin, nearly all having decided antiseptic powers as well as a special action upon the alimentary canal, are prominent among the remedies that have usually accomplished the best results in my hands. In the more recent cases one laxative dose of rhubarb or castor oil has generally proved efficacious as a preliminary measure; and in all cases with much weakness of the circulation, brandy, digitalis, or other cardiac tonic has, of course, been a necessary adjunct.

In the management of these infantile diarrhœas certain hygienic precautions are always important. The flannel belly-band should never be left off, especially at the seashore. The food and drink should be rendered as nearly aseptic as possible. Even with the excellent water now obtainable at Atlantic City, and the fewness of disease germs in the air as compared with that of the large cities, I advise the boiling of all water given to sick babies, whether as drink or mixed with their food.

Infants suffering with entero-colitis are, in nine cases out of ten, bottle-fed, and besides requiring that the bottles and nipples be kept chemically clean, never countenancing, of course, such abominations as rubber tubes attached to the nipples, it is necessary that all forms of artificial food should by some means be rendered aseptic.

Cow's milk, when given to teething infants in warm weather, should be boiled as soon as obtained and then preserved in corked bottles or tightly covered vessels; or better still, the now familiar sterilizing process may be resorted to. It should be borne in mind, however, that except when the milk can be obtained directly from the cow, it is never very fresh, and rarely entirely unaffected by the injurious changes which begin in it as soon as it comes in contact with the air. When from twenty-four to forty-eight hours old, as it usually is when obtained from the dealer, it is such a dubious food, that it may be doubted whether in hot weather any process of sterilization or even peptonization can render it entirely safe and wholesome for sick children. And according to the results of my investigations, it is quite exceptional that the ordinary commercial milk, either in the city or the country, is less than twenty-four hours old when delivered to the consumer. By special arrangement it is sometimes possible to procure it on the same day it leaves the cow, especially when access can be gained to the owner of the animal.

The practice of sending to market directly from the dairy-farm fresh milk carefully put up in sealed air-tight jars, is coming into vogue, and probably in the near future an abundant supply of this kind can be obtained. With such milk the problem of infant feeding will have been greatly simplified.

For some time past, in treating infants in July and August, unless fresh milk could be had from the owner of one or more healthy cows, I have usually made a trial of the least sweet brands of condensed milk variously combined as the case seemed to require. Such trials have rarely disappointed me.

With care to use only a fresh article, and to add to the solution a certain proportion of lime-water, together with, in some cases, barley-water or rice-water, I have seen in midsummer much better results than with any other lacteal combination. At other times of the year, and at any time when the baby and milk-giving animal can be brought near together, I consider good fresh milk, properly diluted and sometimes strengthened with cream and milk-sugar, to be usually preferable to condensed milk or any of the patent infant foods.

An important point in this connection is, that acute gastro-intestinal affections in infants will often respond much more satisfactorily to any treatment, climatic or medicinal, or both combined, if at the outset the patient be deprived of every form of milk for one or two days. The discovery in milk of tyrotoxicon and its highly poisonous action afford a sufficient explanation of the observed clinical fact that in stubborn cases of infantile diarrhœa suitable antiseptics, with a preliminary dose of some laxative —to antidote and sweep out the toxic remains of decomposed milk—will frequently accomplish better results than astringents, and that withholding lacteal food of every sort for a few days is sometimes an indispensable condition of cure. Gum-water, barley-water, chicken-broth, egg-water, a mixture of Bovinine or Murdock's Food with water, and, for older children, stale bread or toast crumbled in the juice from steak or roast beef, are among the substitutes which have often agreed well with my little patients.

In the care of these cases at the seashore it is important to pay more attention to the clothing than is necessary in the cities. This needs to be warmer, particularly at night and when the child is kept at the beach, as it should be the larger part of the time. Improper feeding, and especially over-feeding, often produce relapses at the shore, as they do everywhere. When there is much vomiting, the bottle should be taken away for a time and nourishment administered at frequent intervals by the tablespoonful, or even teaspoonful. When the child is in a hotel or boarding-house, or at points on the beach where many persons pass, it should be protected from the annoyance of being stared at by strangers, an infliction which frets some infants exceedingly. A child worn out by a long siege of diarrhœa has no nerve-strength to be wasted, and all such disturbing causes add to the exhaustion.

Exceptionally, these little patients fail to improve even in the most favored localities, but my later experience is to the effect that when they are sent to Atlantic City before their heart force is so far gone as to be incapable of restoration, they may nearly always be saved.

A PLEA FOR MORE CONSERVATISM IN THE EMPLOYMENT OF TAIT'S OPERATION FOR PELVIC DISEASE.[1]

By W. H. SHARP, M.D.,
PARKERSBURG, W. VA.

Owing to the advance of abdominal surgery, and stimulated by the example of Mr. Lawson Tait, there has sprung up in this country a class of surgeons making a specialty of abdominal surgery. Many of these gentlemen have visited England, tarried at their Mecca in Birmingham, witnessed the marvellous skill of that master, and been dazzled by the celerity with which he operates and the successes following his skill, without profiting, we fear, by the rare judgment he shows in making proper diagnoses of the conditions requiring the operation.

Returning to this country impressed with the importance of these procedures, and anxious to exploit themselves before the public as experts and successful abdominal surgeons, they immediately seek for subjects on whom to exercise their skill and to show their success in curing patients by the removal of diseased organs, as well as to parade a long list of successful laparotomies. Brilliant reports of their cases are prepared and spread before the general profession, and the family physician urged to send the victims of pelvic disease to them for relief.

Some of these younger disciples of Mr. Tait are already rivalling him in the number of successful laparotomies, and every case recovering from the operation itself is heralded as a cure of long-standing and intractable disease. But somehow the reports of the cases end with their dismissal from the specialist's care when the abdominal wound is healed. We learn nothing as to the history of these cases, six months, twelve months, or twenty-four months after; nothing as to the effects upon the system, from thus abruptly changing the whole sexual life of the woman. Occasionally some of the profession more conservative offer a note of warning and protest, but it does not avail much. We are told that Mr. Tait has revolutionized the whole theory and treatment of pelvic inflammations of long standing or of recurrent nature. These gentlemen publishing the reports of such cases—first read before one or more medical societies, then published in some one of the medical journals, then put forth as a reprint and scattered broadcast over the land among the general practitioners—thereby make their cases, methods, and results public property, which should be considered, without reference to the gentlemen offering them, solely from a scientific standpoint. In the *American Journal of Obstetrics*, July, 1889, is an article of this kind, written

[1] At the time this article was written several papers on the subject by other authors, which have since appeared had not been published.

by Dr. B. Curtis Miller, of Charleston, W. Va., entitled "A Year's Record of Seventy-five Successful Cases of Abdominal Section." In a footnote he refers to 144 cases of laparotomy—which, from the text, I judge comprised his cases in a period of from eighteen months to two years. Of the 75 cases reported, 42 were cases of salpingo-oöphorectomy, of which number 27 were for diseased or presumably diseased tubes and ovaries, and 15 for uterine fibroids. Studying this report one is struck with the extreme brevity of the reports of the cases; the meagre character of the information given as to the symptoms demanding the operation, and the absence of details upon the pathological conditions found; nothing told of the previous treatment; and still more glaring is the utter neglect to tell us anything as to the after-history of the patients. For proof of this assertion I quote the following:

"Case II. Both tubes occluded and adherent; ovaries cystic. Case V. Tubes occluded and distended by a dark fluid; no adhesions; ovaries cystic, with small amount of pus. Case XII. Ovaries removed; rapid recovery; no pain since operation."

The latter was a case of dysmenorrhœa in a patient weighing 200 pounds. General health good. No account of condition of ovaries given.

"Case XIII. Ovaries cystic; small quantity of pus observed in right one. Case XIX. Ovaries cystic and considerably enlarged. Tubes in a catarrhal condition."

This appeared to be a peculiar case in that the patient was twenty years old, had been married only nine months, and

"suffered with more or less dysmenorrhœa and leucorrhœa, with constant uneasiness over ovarian region."

Certainly, on the face of the report, it appears as if some less heroic treatment than spaying could have been offered to this patient just upon the threshold of married life with its aspirations of maternity. General practitioners everywhere have seen women so affected conceive, and fulfil the duties of the married state.

"Case XXIII. Mother of two children, a great sufferer from dysmenorrhœa. Both ovaries enlarged and very sensitive."

Could not medical treatment have offered some relief to such a sufferer, save so serious a surgical operation, no matter how skilfully done?

"Case XXVII. Both ovaries greatly enlarged, very soft and spongy."

It appears that the operation was done because of profuse menstruation. No history of prior treatment or of results. Of the fifteen cases done for uterine fibroids there is no history, no reason why the operation was necessary, nor a single word as to the resulting benefits to the patients—whether or not the enforced menopause caused arrest of development. Fibroids have not always become quiescent after the cessation of menstruation. Under "Ovariotomy," our reporter says:

"Nine cases for the purpose of extirpating diseased ovaries or for the relief of troubles arising therefrom."

What troubles we are left to guess. Of what scientific value is such a statement? Under the head of "Miscellaneous Sections" are given five cases for uterine fibroids, with not a word as to what was found or what was done, whether the fibroids were removed, or the tubes and ovaries taken away, or the uterus amputated. I forget Case XVI.:

"Patient had bilateral laceration of the cervix, suffered from various reflex nervous troubles, soreness over lower abdomen, dysmenorrhœa, and difficult locomotion."

On April 14th, he operated on the lacerated cervix; and, not waiting to see what effects were to follow Emmett's operation—effects which, we all know, require weeks, and sometimes months, to develop—or allowing the nervous system to recover slowly from the effects of reflex irritation, this physician, on May 8th, twenty-five days after operating on the cervix, removed the ovaries; one containing one ounce of serum, the other filled with blood and serum. Patient made a rapid recovery. It would appear to an uninitiated general practitioner from this report of the pathological condition that it was necessary for the operator to find something, however slight, to justify this case of spaying.

In fact, this whole report is simply the heralding of the success of the individual operator in performing abdominal section. In the same number of the *Journal of Obstetrics* before cited, is the report of the proceedings of the American Medical Association, where, in the papers read and in the discussions upon the treatment of pelvic abscesses, the same radical treatment is advocated: abdominal section urged in all cases of pelvic abscess, viz., in all collections of pus in the female pelvis; and the drainage of these by vaginal incision, or aspiration through the same canal, condemned in unsparing terms. One acquainted with the names of the gentlemen taking part in the discussion could readily recognize the fact that most of them had been pilgrims to the shrine of Birmingham. A gentleman whom I in former years had the pleasure of knowing, some years since went to Europe and passed some months with Mr. Tait, and has since been devoting himself to abdominal surgery, especially as applied to gynecology. Able, energetic and enthusiastic, he has earnestly, by voice and pen, advocated the views of Mr. Tait. In a paper read before the Cincinnati Medical Society, January 2, 1888, he advocated

"the performance of the operation at the end of from four to six months after the onset of the disease."

Later, in May, 1888, in a paper read before the Section of Obstetrics, American Medical Association, he said :

"I believe that the best plan to pursue in these cases, after a period ranging from twelve to eighteen months of constant and proper care and treatment which is not followed by more than temporary relief, is to advise an operation for the removal of the diseased structures, as the safest and best treatment ; safest because a very small per cent. die if properly cared for, and best because it is a permanent cure."[1]

Certainly the later is the riper and wiser conclusion. In most of these reports the operators end their histories of the cases with their dismissal, the recovery from the operation being complete ; but we are left in the dark as far as the future of the patient is concerned. Are they restored to health and able to resume the duties of their lives? Being in a neighboring town lately, I inquired of several who were in a position to know concerning the health of one of these patients thus operated upon some two or three years since. If my information is correct she is still an invalid—certainly not restored to health, even if relieved of recurrent attacks of pelvic inflammation. In this series of 75 cases of Dr. Miller, 15 are for removal of ovaries and tubes for uterine fibroids. All the comment is :

"That oöphorectomy was performed upon these patients for the premature induction of the menopause, since it *seemed to promise* [italics mine] better results and greater relief than any other method of treatment, when the numerous complications and varieties of disorders noticeable in many of them had been carefully considered."

No information is given as to why the operation was necessary, what complications were noticeable, or what relief was obtained. I know of a number of cases of uterine fibroids under the care of my medical friends, as well as my own, who, with well-considered medical treatment, are getting along fairly well and attending to their household duties. For the benefit of those of the profession who think that nothing can be offered to such patients but removal of the uterine appendages, I commend a careful perusal of the paper of Dr. Bedford Brun, of Alexandria, Va., in *Gaillard's Medical Journal*, 1887 or 1888, on the "Treatment of Uterine Fibroids," or again, to the reports made by those who have used, or seen used, Apostoli's treatment.

In the discussion of Dr. Hall's paper at the American Medical Association, 1888, Professor Goodell, than whom none is more qualified to speak, took conservative ground, saying that he did not believe that because the ovaries or tubes contained serum, blood, or pus, they should for that reason be removed ; he said :

"It is more judicious to give the patient first the benefit of preliminary treatment before resorting to an operation."

And further :

"One reason which should guard us against using the knife too hastily is, life is too dear to be jeopardized by a hasty operation. A certain percentage of women will die after all operations, and, if the truth be always told, a still greater per cent. will, perhaps, be found."

He feared that too many, especially of the younger practitioners, were urged to operate "by papers read." (Above from reprint of Dr. Hall's paper.) Others have also joined in these warnings. In a late number of the *Journal of the American Medical Association* is an able editorial article, entitled "Prurigo Secandi," based upon the warnings of Professor Lefort, in his late editions of *Malgaigne's Surgery*, from which I make the following extracts. The application there is not confined to abdominal surgery. Lefort says :

"When I see the multiplication of successive operations for diseases which a hospital experience of more than forty years has shown me to be either relatively rare, or curable by non-operative treatment, I am led to believe that many of these surgeons, instead of asking themselves what operations the disease and the hopelessness of the treatment compel them to perform on the patient, inquire rather, is the patient one whom they can induce to undergo the operation just then under consideration, not to say in fashion."

The editor, commenting upon the text of Professor Lefort's remarks, further says :

"The fact that an operation is capable of curing the disease is not of itself a justification for the operation. The gravity of the operation must be compared with the gravity of the disease. The benefit to the patient must be proportioned to the danger to which he is exposed."

Certainly this applies to such an operation as the removal of the uterine appendages for dysmenorrhœa, or even a constant pain over the ovaries, or for a persistent menorrhagia. As illustrations showing that well-directed local treatment will, in many instances, so improve the condition, I cite the following histories :

Mrs. X., the mother of three children ; the youngest died in infancy, twelve years previously. She had for some years suffered with painful menstruation, which required her to keep her bed for one day during every menstrual period, which recurred every third week, and was not profuse. At such times she took some anodyne, but formed no habit. I treated her for endocervicitis, without relief to the painful menstruation. She led an active life, attending to her household duties. Later she developed an attack of pelvic inflammation on the right side. This I am certain was specific, her husband being under treatment for gonorrhœa. I aspirated and drew off some pus, more escaping along the track of the needle, *per vaginam*. Under careful nursing, complete rest, hot vaginal douches, and applications of tincture of iodine, and glycerin tampons, together with tonic constitutional treat-

[1] Reports of papers read by Dr. R. B. Hall before the societies mentioned.

ment, she recovered. For several months at the menstrual period she suffered more, and during one or two had a discharge of pus *per vaginam*. She is now as well as before the attack, and leading the same active life.

The following case occurred in the practice of a friend:

Mrs. G., mother of one child, which was fifteen years old. After the birth of this child she had a bad getting-up. Patient had constant pain in the left ovarian region and was treated by several physicians of experience during the following years. Two years ago she came under the care of a physician who found the uterus enlarged, with evidence of former pelvic inflammation—endocervicitis—and a discharge from the uterus of muco-pus. Under local treatment similar to that described above she improved greatly. Being away on a visit to a sister in the city where she had formerly resided, she consulted a man of prominence, who diagnosed an ovarian tumor on the right side, the size of an orange, and advised operation for its removal. Being alarmed, on her return home I saw her in consultation. I found enlargement on the right side, not as large, however, as an orange. The uterus was still enlarged, but it was evident that she had greatly improved under the treatment; I advised its continuance. More than one year has passed; she is better, attends to her household duties, and suffers only with the old pain in the *left* ovarian region.

The following case occurred in the practice of Dr. H.:

Mrs. A., mother of one child; had some stenosis of cervical canal, possibly caused by former applications of nitrate of silver. She was also suffering from some reflex nervous troubles. This condition was treated by gradual dilatation. There developed a swelling as large as a hen's egg on one side of the uterus, with tenderness and pain. Hot applications and rest were followed by a discharge of pus *per vaginam*, judged to be from the uterus. This happened twice while under Dr. H.'s care. The patient said it had happened twice before; the last time while she was under the care of a distinguished gynecologist of one of the Western cities, who had advised removal of the ovary. Under Dr. H.'s care she recovered and for over a year has been perfectly well.

I could cite other cases who were made comfortable, though affected by pelvic troubles, with pain and tenderness as a prominent feature, without recourse to an operation. Patients not robust, it is true, and at times suffering from pain, but able to enjoy life and contribute to the happiness of those around them. Could an operation for the removal of the uterine appendages do more for these patients? I do not wish to deny that this operation is often necessary; but to protest against this tendency on the part of those calling themselves abdominal surgeons, to offer this operation to women who suffer from pelvic pain and pelvic inflammation as the only cure for their troubles. Twenty-five years ago, when I entered the profession, Marion Sims had offered incision or discission of the os uteri as a cure for dysmenorrhœa and sterility. Allured by his captivating writings and brilliant successes, throughout the country enthusiastic followers were cutting the cervix, with results disastrous, or at least disappointing, to their patients. Later, stimulated by the teachings of Emmet, without the restraining influence of his mature judgment, a host of imitators arose who deemed it necessary to excise every bit of cicatricial tissue *and more too*, which accompanied every *slight* tear of the cervix—giving almost just ground for the *bon mot* of the Englishmen—"that Americans slit the cervix to sew it up again." And now another generation appears who are out-Heroding Herod in their anxiety to perform laparotomy in all cases where the patient can be persuaded to part with her ovaries. As further support to what I have written, let the reader refer to a late paper read by Dr. J. M. Baldy before the Philadelphia Obstetrical Society, March 7, 1889, entitled "Complications following Abdominal Section." Dr. Baldy is an experienced operator and knows whereof he writes. He shows the dark side, details the various complications following recovery from laparotomy, which are little, if any, less burdensome to the patient than the original disease. He, in conclusion, says: "When any person about to undergo an abdominal operation must run the gauntlet of all these complications, as well as many more, it becomes a serious matter in deciding for or against an operation. We have here more than the immediate risks to life to consider. We must think—Has his or her present disease been removed, will they be any better off, or may they not be the worse for the interference? At any rate, such a state of affairs should be a warning to inexperienced men not to be misled by brilliant reports seen in the journals, and not to rush thoughtlessly into an operation expecting to produce the same results. They should know that as a rule only favorable cases are reported, and that men do not like to publish to the world their bad work or misfortunes. Abdominal surgery is by no means the easy and simple procedure some men would make us believe, and such an operation should never be undertaken except after careful consideration of all the risks that must be run, the chances of benefit to the patient, and in the presence of actual demonstrable disease. Until the dark sides of abdominal work are well known to the profession at large, the *furor operandi*, which has been so justly complained of, will continue, and many women will succumb to the results of inexperience." And we might justly add, to the results of

inexperience, operating where there is a lack of judgment in the selection of proper cases, or where there is present an overweening desire to perform a brilliant operation—where success will give so much more *éclat* than the same or better results following the slower and safer medical treatment.

NOTE.—After writing the above, looking over some journals of the past year, I found the fullest confirmation of the foregoing argument in several papers to which I must briefly allude. First, to the reports of the discussion on "Nervous Symptoms Arising from Ovarian Disease, and their Treatment" in the Section on Neurology, New York Academy of Medicine, *Medical Record*, June 22, 1889, by prominent neurologists and gynecologists. The question of the removal of ovaries and tubes for neurosis was fully discussed, and the consensus of opinion was very conservative, if not condemnatory. In this discussion, Dr. Field stated that he knew of thirty or forty cases of insanity following the removal of ovaries in patients at the Blackwell Island Asylum. Also, mention may be made of the paper by Professor T. Gaillard Thomas, on "Insanity following Gynecological Operations (see THE MEDICAL NEWS, April 15, 1889), and a report of two cases of insanity following Tait's operation in THE MEDICAL NEWS, November 16, 1889. All these articles, and many similar which may be found in current medical literature, tend to show that Tait's or Battey's operations are not to be lightly or enthusiastically offered to patients as a sure relief to their troubles, for flying from the evils which they know may lead them to a far worse fate.

THE CLINICAL ASPECTS OF THE PRESENT INFLUENZA EPIDEMIC IN WOMEN AND CHILDREN.

BY EDWARD P. DAVIS, M.D.,
PROFESSOR OF OBSTETRICS AND DISEASES OF CHILDREN IN THE PHILADELPHIA POLYCLINIC; VISITING OBSTETRICIAN TO THE PHILADELPHIA HOSPITAL, ETC.

AND

W. S. VANNEMAN, M.D.,
RESIDENT PHYSICIAN IN THE PHILADELPHIA HOSPITAL.

THE prevaling influenza became epidemic in Philadelphia first among the nurses of the Philadelphia Hospital, where the writers had the opportunity of observing its characteristics. The nurses attacked were women, most of them younger than thirty years, in as good general health as the duties of nurses in a large general hospital permit. That it was not an epidemic of nervous deception caused by fear of the affection was demonstrated by the fact that the first cases were not recognized at once as being influenza, and that many of those affected were women especially stolid regarding illness; they were furthermore very desirous to keep on duty and rarely reported themselves as ill until obliged to do so.

Regarding the beginning of the epidemic, the first case was that of an English immigrant who came to the hospital three days after landing at Castle Garden. He had been exposed to cold and wet, and presented symptoms of a severe cold which was followed by pneumonia, from which he recovered in two weeks. Occupying a bed next to him was a patient who was able to serve as waiter in the nurses' dining-room. He had influenza shortly after the immigrant's arrival, and following his attack the nurses were seized by the disease before it became epidemic in the Hospital.

The affection itself had in many cases a prodromal stage of general malaise; others missed this preliminary prostration and were suddenly taken ill. Pain in the cranium, back and muscles usually forced the patient to succumb. This was accompanied by a chill and an elevation of temperature in many cases reaching 104° F., the pulse rarely exceeding 100, the respiration remaining but little accelerated. In uncomplicated cases gradual defervescence succeeded, occupying seventy-two hours on the average; the lowest temperature reached was 96°, usually 97° was the limit. The return to a nearly normal temperature was marked by bronchial catarrh, transient slight pulmonary œdema; nasal and intestinal catarrh in some, intestinal and facial neuralgia, and by a degree of nervous prostration greatly disproportionate with the gravity and duration of the other symptoms. A mild grade of tonsillitis and pharyngitis, and occasionally conjunctivitis, followed the attack. Persistent anorexia, muscular and nervous weakness, characterized the convalescence of most patients; in a few the appetite remained unimpaired through the illness. The average duration of uncomplicated cases was from four to seven days. The percentage of complicated cases in the series studied, numbering forty cases, was 12.5 per cent.; the percentage of relapses was 2.1 per cent.

A noticeable feature of the epidemic has been the absence of nasal catarrh in many cases, while bronchial catarrh has been especially well marked. The complications observed have been severe follicular tonsillitis, catarrhal, lobular pneumonia, and an accentuated first sound of the heart, with evidences of a beginning mitral obstructive lesion in one case. These complications have not assumed a severe type; one case of catarrhal pneumonia is persistent, and gives rise to a suspicion of tubercular infection. In a case which had a second attack, it is curious to note that catarrh, nasal and bronchial, was present in the first but not in the second attack; the latter was characterized by severe headache and muscular and neuralgic pain. In many cases menstruation was precipitated by the illness.

In general, the epidemic among the nurses bore the characteristics of an infection of varying severity, the effect of the infective agent upon the nervous system resembling somewhat that produced by diphtheria. Defervescence in these cases was followed by prostration disproportionate to the degree of fever; the special senses occasionally suffered, the abolition of taste being especially frequent. Severe conjunctivitis occasionally followed an apparent convalescence. Loss of weight generally occurred, to the extent of one-twentieth or one-twenty-fifth of the body weight. The secretions and excretions were those of any similar fever; commencing defervescence was frequently ushered in by profuse perspiration. Regarding treatment, antipyrin, antifebrin, and phenacetin were used to relieve the pain and fever of the first stage, the best results being obtained by antipyrin in five-grain doses. So soon as the fever declined, quinine, iron, and strychnine were persistently given, with easily digested food (milk and soups) and occasionally red wine. The mouth was rinsed and the throat gargled with equal parts of a saturated solution of potassium chlorate and boric acid, with glycerin. Symptomatic treatment was added to this routine as needed. In the bronchitis which so frequently followed the febrile stage the best results were obtained by ammonium chloride given in plain soda water, without syrups. Among the nurses the tediousness of convalescence was very marked, persistent tonic medication being required for ten days or two weeks after hospital work was resumed.

In addition to this epidemic among hospital nurses, other cases in women present points of interest. In a woman aged sixty-eight, vesical irritability with great prostration were the first symptoms observed. Continued fever (101° and 102° F.) followed for four days; convalescence has been very slow, with no nasal and but little bronchial catarrh, diagnosis in this case being based upon symptoms of a constitutional infection. Influenza does not seriously complica' normal abor or the puerperal state. In a recent uncomplicated labor no elevation of temperature or complication, except bronchial catarrh, followed delivery, although the mother suffered from influenza. Her child, on the fourth day, manifests no symptom.

That influenza may give rise to serious pneumonia in the puerperal state is exemplified by the case of a primipara. Suffering before labor from nephritis, asthma, and hydramnios, with contracted pelvis, delivery was difficult, the position being occipito-posterior and necessitating the forceps. Chloroform was used preferably to ether and delivery was safely accomplished. Severe bronchitis, with constant tendency to catarrhal pneumonia, supervened, from which the patient is making a difficult recovery. An example of the gravity of influenza when added to an impaired condition of the heart is shown by a young woman, apparently in good health, who visited my office recently for advice concerning a beginning bronchitis of influenza. While narrating her symptons angina pectoris suddenly developed, and for several hours her condition was one of great suffering and considerable danger. A peculiar harsh, brassy cough followed the pain and dyspnœa, and as respiration and cardiac action became better she was taken to her home in a carriage. She, too, presented unmistakable symptoms of a severe infection. In young children influenza may run its typical course, speedy convalescence following. Such has been the history of the majority of cases in carefully nursed infants in the Philadelphia Hospital, simple remedies sufficing to relieve symptoms. Occasionally a severe broncho-pneumonia results, as in a recent fatal case in which persistent high temperature (104°, 105°, and 106° F.) resisted all efforts at reduction. The child nursed eagerly, remained conscious, but was constantly pallid and asphyxiated. The persistence of the fever in this case was very noticeable. In older children pneumonia often follows influenza and proves unusually prolonged and intractable. A recent case of pulmonary tuberculosis in a boy aged eight years was complicated by influenza.

Severe bronchitis and broncho-pneumonia in those portions of the lungs not apparently infected by tubercle followed influenza, and severe illness resulted, from which recovery was slow. In cases in children who are not enjoying the benefits of the constant care of trained hospital nurses, the following formulæ have been found of value, and may be entrusted to even ignorant mothers:

For simple bronchitis of larger bronchi, with headache, fever, and restlessness:

R.—Acid. hydrobromic. dil. . . ♏ 10.
Syrup. scillæ . . . . ♏ 10.
Aquæ . . . . ad ʒ 1.—M.

Every two hours, if required.

For capillary bronchitis with threatened suffocation, Henoch's powder is useful:

R.—Camphor pulv. . . . gr. ¾ to 1.
Acid. benzoic. . . . gr. ¾ to 1.
Sacch. alb. . . . gr. 7½ to 10.—M.

In ten powders. One powder every two hours.

To this should be added the free use of whiskey and ammonia, a cotton or oiled silk jacket worn over the chest, and inunctions with camphorated oil; in severe cases croton oil diluted with olive oil may be applied over the sternum once or twice.

In conclusion, it may be remarked that, while evidence of distinct contagion is lacking, the coincidence shown in the arrival of the immigrant and the development of the epidemic at the Philadelphia

Hospital is interesting. As has been observed by others, evidences of infection, varying in degree and in organs whose functions were deranged, but affecting chiefly the nervous system, were constantly and unmistakably present.

MEDICAL PROGRESS.

Treatment of Buboes by Iodoform Vaseline.—The following is Professor Pontain's "rapid method" of curing buboes: 1. Washing and disinfection of the region by means of hot sublimate solution (1 : 2000). 2. Puncture with the lancet if the skin is soft; with the straight bistoury if the pus is deeply situated. The puncture is small and made in the most fluctuating point. 3. Evacuation of the pus, gently pressing out completely the contents of the ganglion. A few injections of sublimate solution are now made to wash out the cavity. 4. Injection of iodoformized vaseline melted by heat. The oil is to be gently injected in by means of a glass syringe previously charged and placed in hot water. 5. Dressing with absorbent cotton. As soon as the cavity is full of the iodoformized vaseline, a wad of cotton, soaked in sublimate solution 1 : 1000, is placed over the bubo, and kept in place with a spica. The contact of the cold congeals the vaseline, and makes a plug at the orifice of the abscess. After the first day all pain disappears, and, usually, healing is complete in six or seven days. In some cases it is necessary to renew the injections of vaseline. Out of forty-one buboes thus treated by the author, more than half were cured in less than five days. The most rebellious required twenty-three days.—*Journal of Cutaneous and Genito-urinary Diseases*, December, 1889.

Creolin in Gynecology.—Extensive experiments have been made by CHÉRON with creolin in two and five per cent. solutions. The weaker solution was used for vesical injections in cases of gonorrhœa. Neither poisoning nor pain resulted; the discharge from the urethra diminished and soon disappeared, injections being made every other day. Gonorrhœal vaginitis was quickly improved by irrigation of the vagina and vulva with the five per cent. solution. In purulent cervical endometritis the diseased tissues were first carefully cleansed with absorbent cotton, after which an application of the five per cent. solution was made. After a few applications the suppuration ceased. Creolin gauze was found to be an excellent substitute for iodoform gauze in cases of suppurative and hemorrhagic endometritis in which a tampon was required. From the foregoing it was concluded that creolin has a very positive effect upon the microbes of gonorrhœa and of pus, and that in ordinary doses it is neither painful nor toxic.—*Annals of Gynecology*, December, 1889.

Effects of Chloralamid and Somnal.—One of the most careful clinical studies of the two new hypnotics, chloralamid and somnal, yet reported has been made by Dr. ADOLPH ROBINSON, of Berlin (*Deutsche medicinische Wochenschrift*, December 5, 1889), who, after numerous observations upon fifty patients suffering from many diseases, concludes that:

1. Chloralamid frequently causes a weak pulse; somnal, even in the same patients, has no noticeable effect upon the circulation.

2. The hypnotic effects of the drugs are about equal, neither producing a sound sleep.

3. Vomiting within an hour after the ingestion of either drug is not uncommon and is sometimes violent. In the cases where vomiting is not produced, loss of appetite, nausea, gastric pain, giddiness and headache on the following day are frequent. These effects are more frequent after the ingestion of somnal than after chloralamid.

Quinine in the Treatment of Syphilis.—A writer in the *Vratch*, November 21, 1889, recommends quinine in the treatment of syphilitic patients in whom cachexia and fever are marked symptoms. The quinine should be administered in doses of from fifteen to twenty grains daily, associated with mercurial inunctions. The drug prevents ptyalism and stomatitis, and, if ulcers are present, hastens their cicatrization. Quinine is useless in ordinary cases of syphilis.—*Bulletin général de Thérapeutique*, October 13, 1889.

Weil's Disease.—DR. WEISS, of Prague, who has made a careful study of Weil's disease, classifies and describes the symptoms thus:

1. The febrile symptoms are marked at the beginning of the disease, the fever being characterized by morning remissions. Between the fifth and seventh day the temperature begins to fall, reaching normal about the tenth or twelfth day. In some cases, after a period of normal temperature, there is a second accession of fever, seldom, however, a true relapse.

2. Pain in the limbs is a distressing symptom, rendering pressure or motion unbearable to the patient.

3. Gastro-intestinal symptoms are seldom distinct.

4. Jaundice is the most characteristic symptom, and is in all cases icterus from obstruction. Associated with the jaundice is swelling of the liver, the size of which depends upon the amount of biliary retention.

5. The swelling of the spleen, which is acknowledged by all authors, appears early and is a strong point in favor of the infectious nature of the disease.

6. Nephritic symptoms, such as hemorrhagic nephritis, are common and often very serious.

Bronchitis, epistaxis, herpes, purpura, petechia, and erythema, as accidental complications, have all been observed. The statistics of the epidemics in Prague show that men between the ages of twenty and thirty-five years are most frequently affected, and women and children less frequently.

The greater number of cases are seen in the summer months, but sporadic cases develop at any season. Epidemics of the disease are unquestionably caused by bad sanitation. It is infectious, but its contagiousness is as yet undecided.—*Wiener medizinische Presse*, November 17, 1889.

Naphthol-camphor as a Surgical Dressing.—DR. SCHWARTZ has been using for a year, and with very satisfactory results, naphthol-camphor as a surgical

dressing. The naphthol-camphor is prepared by mixing one part of beta-naphthol with two of camphor, the combination making a brownish transparent fluid which readily saturates dressings. Schwartz has used this fluid as an application in cases of tubercular ulceration, cold abscesses, and suppurative otitis media. Ulcers, he states, should be dressed with gauze soaked in the solution, covered with protective and the whole with cotton wadding. This should be changed every day or two. Immediately after the application the patient feels a slight burning, which, however, soon disappears. According to Schwartz, the naphthol-camphor causes a luxuriant growth of healthy granulations, and cicatrization progresses at least as well as with iodoform dressings. Large quantities may be applied without danger of toxic symptoms. Occasionally a slight erythema appears upon the surrounding skin, which can be avoided by the use of borated vaseline. For suppurative otitis the ear should be syringed with a warm boric acid solution, after which the naphthol-camphor is dropped into the ear and the meatus closed with a cotton pledget. Discharge, offensive odor, and pain quickly disappear.—*Wiener medizinische Presse*, December 1, 1889.

Intra-laryngeal Injections of Menthol in Phthisis.—MR. WALKER DOWNIE, in the *Glasgow Medical Journal*, December, 1889, reports excellent results in the treatment of tubercular laryngitis and early phthisis with the intra-laryngeal injections of solutions of menthol in olive oil. To the solution he usually adds pure creasote in the following proportions:

Creasote	2 parts.
Menthol	12 "
Olive oil	86 "

An ordinary hypodermic syringe with a detachable vulcanite laryngeal tube is the most satisfactory apparatus. In administering the injection a laryngeal mirror should be used, by means of which the curved nozzle can be guided into the larynx without coming in contact with the tongue or fauces, thus obviating all risk of retching. The point of the syringe should be just below the vocal cords when the fluid is injected. If the fluid is applied to the cords, it produces a choking sensation, often with spasmodic cough. From twenty to thirty minims should be injected at intervals of a few minutes until a drachm and a half has been used. The patient's immediate sensations are a comfortable warmth throughout the chest, loss of inclination to cough, and disappearance of "tightness" of the chest, if it existed. Cough is often absolutely checked for from four to eight hours. Expectoration is reduced in amount and purulency. The majority of patients gain in weight, and high temperature is often permanently reduced during treatment.

The probable explanation of these effects is that the menthol acts as a local anæsthetic to the mucous membrane of the larynx and bronchi; that it is a powerful, though harmless, stimulant; and that it is an antiseptic which, being very volatile, is rapidly diffused throughout the lung.

Resorcin in the Treatment of Whooping-cough.—DR. CONCETTI, in the *Wiener medizinische Blätter*, asserts his belief that resorcin administered internally is preferable to any other remedy in the treatment of whooping-cough. He has employed the drug in forty-eight cases—among them an infant of twenty days of age. The daily dose varied according to the age, ordinarily 7½ to 22 grains, dissolved in a considerable quantity of water, being given. The doses were given from one to two hours apart, according to the intensity of the case. In thirty-four cases the affection occurred in its typical form, with repeated spasms of coughing, accompanied by the characteristic whoop. In twelve of these treatment was commenced in the catarrhal stage before the characteristic sound appeared. The whoop subsequently appeared, but only for a few days (from six to fifteen); it was by no means severe, and the attacks occurred but seldom. In the other twenty-two cases treatment commenced in the second stage, which, in some cases, had already lasted a week or more. In these latter cases the action of resorcin was most evident, since the attacks rapidly diminished both in intensity and frequency, while other methods of treatment which had hitherto been employed in the same cases remained absolutely without effect. The author likewise states that the duration of the disease was positively shortened, some cases lasting but one week, others two, or more seldom, three weeks; in the latter cases leaving a light catarrh, which readily yielded to ordinary remedies. Dr. Concetti suggests that perhaps the results obtained by Moncorvo and others from the local application of resorcin in whooping-cough are to be attributed to the amount of the drug which had been swallowed.—*Therapeutic Gazette*, December, 1889.

Treatment of Infantile Diarrhœa.—In a paper on the fermentative diarrhœas in infants, read before the Harveian Society, DR. LUFF, while admitting that though probably several irritating substances resulting from the fermentation of milk are factors in the production of the form of acute infantile diarrhœa under consideration, contended that the principal cause was the milk or cheese ptomaine, tyrotoxicon, produced during the fermentation of milk under certain conditions. The treatment of acute infantile diarrhœa with the view of arresting the abdominal intestinal fermentation was then considered. Carbolic acid, creasote, resorcin, salicylic acid, salicylate of soda, naphthol, and salol have been given in the hope of checking the putrefactive changes in the bowels. Ringer has recommended the administration of a weak solution of bichloride of mercury in infantile diarrhœa attended with very slimy stools. Dr. Luff then referred to Illingworth's antiseptic treatment of infantile diarrhœa, which he had himself found most useful, and the employment of which had first directed his attention to the treatment he now employed. This treatment consists in the administration of $\frac{1}{50}$ of a grain doses of the biniodide of mercury dissolved in iodide of potassium, combined with one-grain doses of chloral hydrate. It was shown experimentally that the soluble biniodide of mercury is an extremely soluble and diffusible salt, and that it possesses the property of combining with and rendering insoluble the milk ptomaine, tyrotoxicon. He has never found that the soluble biniodide of mercury itself acts as an intestinal irritant. Of eighty cases of acute infantile diarrhœa treated by this method, the diarrhœa ceased within two days in seventy-two of the cases; in five of the remaining eight cases it ceased within four days, and in no case did it last over seven days.—*Lancet*, December 21, 1889.

Influence of Massage on the Secretion of Urine.—POLOUBINSKI has recently studied the influence of massage on diuresis, and his results, which indicate that massage of the abdominal region increases the urinary secretion, are published in the *Bulletin Général de Thérapeutique*, October 15, 1889. Experiments were made upon ten individuals whose renal organs were perfectly normal. During the entire duration of these experiments the diet of these persons was precisely the same in all cases. The abdomen was subjected to massage daily, the duration of each *séance* being about half an hour. The author believes massage not only increases the quantity of urine, but also the solids, urea, and especially the nitrogen eliminated in the urine. Massage of the lumbar region had no influence whatever upon the urinary secretion.—*Therapeutic Gazette*, December, 1889.

Insufflation of Salt in the Treatment of Neuralgia.—At a recent meeting of the Edinburgh Medico-Chirurgical Society, DR. GEORGE LESLIE gave the details of thirty or forty cases of facial and other neuralgias, cephalalgia, odontalgia, etc., which had been cured, in most instances instantaneously, by insufflation of powdered common salt through the anterior nares. The salt was either "snuffed" or blown up the nostrils. He had been unsuccessful in only two cases; both of these were cases of old standing, which had been treated frequently by morphine injections. In one of them excision of the nerve had been practised.—*British Medical Journal*, December 14, 1889.

Treatment of Baldness.—The following is LASSAR'S treatment for baldness:

First. A strong tar soap is applied to the scalp for at least ten minutes.

Second. Removal of the soap by a tepid water douche, the water to be gradually cooled, and the scalp well dried.

Third. The scalp is shampooed with the following mixture:

R.—Bichloride of mercury	. .	10 grains.
Glycerin, Alcohol	. . of each	2 ounces.
Water	. . . . .	5 ounces.

Fourth. Shampoo with absolute alcohol, to which one-half per cent. of naphthol has been added.

Fifth. The following solution is well rubbed into the skin:

R.—Salicylic acid	. . . .	30 grains.
Tincture of benzoin	. .	1 drachm.
Neat's-foot oil	. . .	3 ounces.

—*Provincial Medical Journal*, December 2, 1889.

Salol in Gonorrhœa.—DR. DREYFOUS, of Paris, advocates the treatment of gonorrhœa with large doses of salol. Dr. Dreyfous has tested the effect of salol administered alone, and in other instances he has given it simultaneously with copaiba and cubebs in order to hasten the cure. He recommends the use of salol to surgeons who operate on the urinary organs; it renders urine aseptic, which is thus innocuous when in contact with raw surfaces.—*British Medical Journal*, December 7, 1889.

Auscultatory Percussion.—KARL CZOBOS (Gyógyászat No. 42) describes a method of auscultatory percussion which he considers of especial value in the diagnosis of disease of the pulmonary apices. It is practised by placing the ear posteriorly between the scapulæ and percussing with two fingers on the anterior surface of the chest, beginning at the clavicle and percussing each side alternately. No pleximeter is used. The sound heard in this manner is entirely different from that heard in the usual manner of percussing, the pitch changing as the alveoli are filled and emptied during respiration. Over a healthy lung the tone is peculiarly resonant, of a metallic quality, and more intense in inspiration than in expiration. If infiltration is present, the sound has a singular dull quality as of solid metal striking a hard body. An unusual amount of fat over the clavicle does not change the tone, and in patients without much fat the method can be used over the entire chest.—*Prager medicinische Wochenschrift*, November 27, 1889.

The Effects of Phenacetin.—DR. K. C. BOSE, in a paper read before the Calcutta Medical Society, summarizes the advantage of phenacetin over other antipyretics thus:

1. It causes a gradual reduction of temperature, and the rise after the effect passes off is also gradual.
2. In ordinary doses, it never causes alarming symptoms.
3. It is tasteless, and for that reason easily given to children.
4. A full dose to a delirious person usually produces a quiet night.
5. It does not cause much sweating.
6. No effect is produced by the drug upon the heart.
7. No gastric disturbances are caused by it.—*Indian Medical Gazette*, September, 1889.

Administration of Chloral in Infantile Convulsions.—WIDERHOFER, of Vienna, recommends the following, as a sedative in infantile convulsions:

Hydrate of chloral	. . . 1 drachm.
Distilled water	. . . 3 fluidounces.
Syrup of bitter orange peel	. 1 fluidounce.

A teaspoonful every two hours.—*Revue Générale de Clinique et de Thérapeutique.*

Sleeping Draught.—YVON uses, for adults, a sleeping draught made as follows:

Hydrate of chloral	. . . 1 drachm.
Bromide of sodium	. . 1 "
Syrup of codeine	. . . 5 drachms.
Syrup lauro cerasi	. . . 5 "
Water	. . . . . 4 ounces.

—*Revue Générale de Clinique et de Thérapeutique.*

Prescription for Asthma.—

Hydrate of chloral	. . . 30 grains.
Iodide of sodium	. . . 22 "
Simple syrup	. . . . 4 ounces.

In an attack give a tablespoonful every hour.—*Revue Générale de Clinique et de Thérapeutique.*

Injection for Infantile Convulsions.—

Musk	3 grains.
Hydrate of chloral	10 "
Camphor	15 "
Water	5 ounces.

—*Rev. Gén. de Clinique et de Thérapeutique.*

Suppositories of Chloral.—YVON, recognizing the irritation apt to be set up by chloral when given by the rectum, recommends the following:

Hydrate of chloral	7 grains.
Extract of belladonna	3 "
Cacao butter	45 "

—*Revue de Clinique et de Thérapeutique.*

Sweating of the Feet.—LEGOUX, writing to the *Revue de Clinique et de Thérapeutique*, recommends the following for sweating of the feet:

Liquid perchloride of iron	1 ounce.
Glycerin	3 drachms.
Essence of bergamot	6 "

This is painted over the feet and between the toes. The feeling of heat and soreness is removed at once, and comfort is soon obtained for long marches.

Two Cases of Intestinal Obstruction Cured by Injections of Sulphuric Ether.—CLAUSI, in *Il Morgagni* for September, 1889, reports the cure of two cases of obstinate obstruction by the injection of 3 drachms of ether and alcohol in 10 ounces of water by means of an ordinary syringe. The patients felt a sensation of warmth in the entire belly, and immediately belched up air loaded with the odor of ether. A movement of the bowels soon afterward followed.

Creasote in Phthisis.—GILBERT recommends, in the *Revue de Thérapeutique Médico-Chirurgicale*, the following prescription for phthisis:

Creasote	½ drachm.
Rum	1 "
Syrup of tolu	½ "
Water	6 drachms.

A tablespoonful in a wineglass of water.

Or,

Creasote	½ drachm.
Arsenite of soda	½ grain.
Huxham's tincture	8 ounces.
Malaga wine	8 "

A wineglassful with the meals.

Treatment of Diphtheria and Croup.—According to the *Journal de Médecine de Paris*, GALLOIS recommends the following solution for application to the areas of mucous membrane involved:

Crystals of thymic acid	15 grains.
Essence of thyme	1 drop.
Alcohol	1 ounce.
Dissolve, and add of water	2 pints.

For application to the nasal cavities, this must be modified as follows:

Acid. thymic.	7 grains.
Alcohol	½ ounce.
Sea salt	1½ drachm.
Water	1 quart.

This should be applied about every three hours.

Lotion for Pruritus Vulvæ.—

Carbolic acid	15 grains.
Tincture of opium	4 drachms.
Dilute hydrocyanic acid	2 "
Glycerin	4 "
Distilled water	4 ounces.

Mix and apply as a lotion, or the following may be used:

Hydrochlorate of cocaine	7 grains.
Lanolin	1 ounce.

Make into an ointment, and apply a small quantity of the ointment to the area involved.—*Gazette de Gynécologie.*

Powder for Coryza.—The following prescription for coryza is quoted in the *Journal de Médecine de Paris*:

Naphthalin, finely pulverized Boric acid	āā 25 parts.
Pulverized camphor	1 part.

To which may be added one or two minims of essence of rose. A pinch is to be occasionally snuffed into the nostrils.

Operation for Prolapse of the Rectum.—M. VERNEUIL, at the Société de Chirurgie, described a new method of treating rectal prolapsus, by attaching the adhesions of the posterior surface of the rectum to the corresponding portion of the pelvis. After reducing the intestine, the portion of the anal orifice to be excised is determined. A triangular fragment is then traced by means of two transverse incisions passing through the posterior portion of the anal orifice, and two others passing from the extremities of the two first to the point of the coccyx. When the rectum is exposed, four horsehair sutures are introduced into its wall and placed at intervals of about half an inch from each other. The intestine is raised by drawing all the threads toward the concave portion of the sacrum. In order to fix the intestine permanently, the threads are drawn through the skin to the right and left of the wound, one and three-quarters inches distant from the median line, with Emmet's needle. Thus four handles in the form of a U are contrived, which may be tightened at will. The fragment traced as above described is then detached at the base. The ano-coccygeal wound is closed by transverse sutures. A large drain is placed at the back of the rectum, in order to form a track which will sustain and increase the adhesions. The anal orifice is contracted by horsehair suture. M. Verneuil obtained good results in a case which had lasted four months with this method, which he names "posterior rectopexia." At the same meeting M. Delens recommended the following method in cases of voluminous prolapsus. He applies fuming nitric acid to the tumor, reduces and plugs the anus, and administers opium in order to prevent the occurrence of stools during at least eight days. M. Schwartz has obtained good results by making scores with the thermo-cautery on the projecting intestine, and pushing backward the anus toward the coccyx, the old orifice being closed by perineorrhaphy. M. Segond considers that ablation should be practised in order to perform colopexia with success. —*British Medical Journal*, December 21, 1889.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

"MENTAL HEMIANOPIA."

IT is with much regret that we note the practical failure of the work of the commission appointed by the New York Neurological Society in March, 1887, to investigate the claims of Dr. George T. Stevens that "difficulties attending the functions of accommodating and adjusting the eyes in the act of vision, or irritations arising from the nerves involved in these processes, are among the most prolific causes of nervous disturbances, and, more frequently than other conditions, constitute a neuropathic tendency." The November number of *The Journal of Nervous and Mental Diseases* is devoted to its report, with some preliminary notes, and we give elsewhere a summary of the report of Dr. Stevens's protests, and the discussion at the meeting of the Neurological Society, on Nov. 5, 1889, when these were presented. The inquiry grew out of a paper read by Dr. Stevens on "Irritation arising from the visual apparatus considered as elements in the genesis of neuroses," in which extreme claims were made as to the importance of ocular strains and the great benefit of their correction for the relief of insanity, epilepsy, chorea, and other nervous disorders; and a commission consisting of Drs. Seguin, Birdsall, Starr, W. O. Moore, D. Webster, C. L. Dana, and F. P. Forster, was appointed to investigate the matter, by submitting cases of such disorders to Dr. Stevens for treatment, and studying the results.

It was to be anticipated that difficulties would arise in the investigation, and that the result reached would not obtain unanimous acceptance either for its facts or its deductions: the personal equation forms so large a factor in judgments as to functional nervous troubles that the most competent and honest observers might well differ as to the first and last states of the patients studied; and the statements of such patients about themselves, which would form not a little of the evidence, must of necessity possess but limited value. Still, it was not unreasonable to expect a report made in judicial spirit, and set forth with sufficient accuracy to secure respectful attention.

Such a hope is hardly realized; and the phrase of our heading, which Dr. Stevens uses to characterize the views of the commission, must appear to have some justification even to those not at all inclined to take his part in other respects. The unfavorable report gives evidences of serious inaccuracies, and the inclusion of the series of cases admittedly "not counted," savors strongly of bias and injustice. During the two and a half years the commission furnished but twenty-eight cases—five choreic and the rest epileptic—and only one-half of these were available for the study; and this poverty of material, coupled with the withdrawal of at least one suitable case, goes to show, as he claims, that ordinary, typical cases were withheld in order to increase the difficulty of his task. In the Neurological Society, the small assemblage which met to hear the report, and accepted it by a vote of five to four, is another of the unfortunate aspects of the affair, which detracts greatly from the weight of the judgment which has been passed against Dr. Stevens's claims. That these claims were apparently extravagant, and advocated by Dr. Stevens and his followers with more zeal than discretion, should have had little influence with this commission, which offered to put them to a judicial test; and the room for cavil which the report affords will rob it of much of its weight with the unprejudiced, while it awakens some sympathy with Dr. Stevens as having met with scant justice.

The real result of the whole matter is not very difficult to discover, however. The terms upon which Dr. Stevens was willing to undertake the test indicates a standpoint much less advanced than that which underlies some of his utterances; and there is unanimity in the opinion of some of the members of

the commission—those who on entering it inclined to favor his views having no word of dissent from the condemnatory opinion of those whom he looked on from the start as his antagonists. The President of the Society in 1887, who, acting in Dr. Stevens's interest, was largely instrumental in setting the inquiry on foot, who was added to the commission as Dr. Stevens's choice, and who furnished nearly one-half of the cases studied, stated in the discussion that he had lost most of his faith, as he had seen no case much improved under Dr. Stevens's treatment.

To a looker-on there is not a little rather amusing in the controversy, as the matter may be termed. Dr. Stevens would seem to have been the first to call the attention of many of his fellow-townsmen to the fact that there are ocular muscles, and that these are not infrequently out of perfect order. His "discovery" and "the Stevens method" are quoted with awe by many who do not count themselves his disciples; and the zealous advocacy in word and deed of "graduated tenotomy," "the Stevens operation," by his followers has made "muscle-nicking" a town topic in lay circles. Patients as well as medical men have been infected by Dr. Stevens's enthusiastic confidence in his views, as evinced by their submission to series of operations sometimes numbering a dozen or more; and he has, at least, succeeded in awakening in some ophthalmologists a better appreciation of a neglected subject than would probably have resulted from decades of less sensational advocacy.

THE TREATMENT OF SNAKE-POISONING.

While it is perfectly true that snake-poisoning is a fortunately rare occurrence in this part of the country, it is equally a fact that in the western portions of the United States persons suffer quite frequently from accidents of this character, and it is, therefore, of importance that some knowledge of the proper treatment of such cases should be sought after. Among the laity, particularly of the less educated classes, the survival of an animal or man who has been bitten by a snake after the administration of the simplest form of remedy is an argument of such *post hoc propter hoc* force, that the witnesses are forever willing to stake their reputations as to veracity on the efficacy of the measure or drug, and to act as missionaries in the promulgation of its valuable powers among their fellows. As a result of this, a very large number of so-called remedies are to be met in every region where poisonous snakes abound.

The well-known studies of Weir Mitchell, carried on during many years, culminating finally in the joint paper written with Reichert, reached three conclusions which are worthy of note in this connection; namely, that, as the poisons act directly upon the blood, disorganizing it, the fatality of the case must depend largely upon the quantity of the poison introduced into the blood, be the antidote what it may; that the secret of successful treatment lies in the antagonizing of the poison in the wound before the toxic agents gain entrance to the blood, and, above all, that the substance to be used for this purpose is permanganate of potash. It is unnecessary to add that stimulants, external heat, and other means dictated by common sense are to be employed.

We have called attention to this matter because in another column will be found a letter from Dr. Mitchell, which is self-explanatory, and one from an army officer who has had a wide practical experience concerning the matter under consideration.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Meetings of November 5 and December 3, 1889.

The President, George W. Jacoby, M.D., in the Chair.

In March, 1887, a commission consisting of Dr. E. C. Seguin, Chairman, Dr. M. A. Starr, Secretary, and Dr. W. R. Birdsall, together with two ophthalmologists, Drs. W. O. Moore and David Webster, and two other gentlemen nominated by Dr. Stevens, viz, Drs. C. L. Dana and Frank P. Foster, was appointed by the Society to investigate, in conjunction with Dr. G. T. Stevens, the treatment of ocular irritations as a therapeutic measure in certain neuroses. This commission presented its report on the

TREATMENT OF EPILEPSY AND CHOREA BY THE CORRECTION OF OCULAR DEFECTS

in November, the discussion being concluded at the December meeting. Immediately preceding the reading of the report the following protest was presented by Dr. G. T. Stevens:

"Mr. President and Gentlemen of the Neurological Society: I respectfully protest against the reception of the report now announced, for these reasons: 1. That the commission having failed to perform its part of the agreement upon which the report is to be founded, the report is not now in good order; 2. Because the report is not a report on the proposition at issue; 3. Because the report is inconsistent with the facts and is mislead-

ing; and, 4. Because it is an *ex parte* report and objectionable in spirit and motive."

The President then called for the report of the commission, which was read by its chairman, Dr. E. C. Seguin. The more important features of this report were as follows:

After a plan of proceedings had been agreed upon between the commission and Dr. Stevens, the members began to send patients to the latter in April, 1887.

Each patient was examined by two neurologists, who agreed upon the diagnosis and compiled a history of the case. The patient was then sent with the history to Dr. Stevens, who examined the ocular conditions. Subsequently, the ophthalmologists of the commission examined the eyes and reported their results to the secretary, who added these notes to the copy of the history in his possession. When an operation was undertaken, notice of it was sent by Dr. Stevens to the secretary, who, in turn, notified the ophthalmological members and also the neurologist who had furnished the patient. These members then attended the operation and noticed the conditions found in the eyes before and after it, sending their records to the secretary. Their non attendance, however, did not prevent operations from being done, and the records of these operations, as well as records regarding prisms and glasses prescribed by Dr. Stevens for the patient, the commission had been unable to obtain from him.

The patients from time to time visited the members of the commission by whom they were sent to Dr. Stevens, and notes of the conditions found were made and sent to the secretary. In the cases of epilepsy the record of attacks had not in all cases been kept in duplicate, Dr. Stevens having the record on the blanks furnished by the commission, and in these cases the records had not been accessible.

The total number of patients examined by the commission and sent to Dr. Stevens for examination was 28; 23 epileptics and 5 cases of chronic chorea.

All were found to have ocular insufficiencies. 5 were withdrawn without treatment; 3 a month after examination; 1 two months after; 1 three months after; 2 four months after; 1 five months after.

The reasons for withdrawal were as follows: 5 were unable to attend regularly; 2 were declined by Dr. Stevens on the ground of organic disease; 5 were withdrawn by mutual consent of member sending case and Dr. Stevens for satisfactory reasons, such as non-attendance; 3 were discontented because of increase of symptoms.

Hence, of the 28 cases there were only 14 who were treated for four months or over, and these were the only ones available for conclusions. These cases were tabulated, and the results summarized thus:

	Cured.	Much Improved.	Improved.	Unimproved	Unknown.	Total
Chorea .	None.	1	2	2	0	5
Epilepsy .	"	None	3	5	1	9
Total .	None.	1	5	7	1	14

Of the six improved cases three had been presented to the commission by Dr. Stevens from his private practice, with no exact data, and the degree of improvement could not be ascertained. In the other three reported as improved, in one improvement began after thirty weeks, and the patient had never been entirely free from chorea for one month; she had at times been better under the ocular treatment, at times worse, even now having choreic movements, usually before menstruation. In another the chorea was only slightly less than at the outset. The sixth case, an epileptic, was having about the same number of attacks as she had had under bromide treatment, but far less than when under no treatment whatever.

Regarding those not improved, many of the patients would say they felt better, in spite of the written records proving the increased frequency of the attacks. This was in part due to increased hope and confidence in the success of the treatment, and also to the freedom from depression of mind and bodily functions produced formerly by the use of the bromides. Others had complained much of headache and vertigo which had appeared during the treatment, and in several diplopia had been produced and still remained. A few of the patients had been made exceedingly miserable by great increase in the frequency and severity of the attacks, which had finally necessitated an abandonment of the ocular treatment and a return to drugs. This statement applied to a number of cases which had been withdrawn.

It would be noticed that none of the cases having been cured, all remained indefinitely under treatment, a perfect permanent ocular equilibrium not having been secured in any case. If it were impossible to secure such equilibrium, a cure could not be expected, granting the theory of Dr. Stevens. If it were possible to secure such equilibrium, it was to be supposed that it could be secured in at least two years; yet four of these cases had been under constant treatment for two and a half years without this result.

In conclusion the committee expressed the opinion that as far as this investigation had warranted a conclusion, the method of Dr. Stevens does not afford a sufficient degree of relief to patients suffering from chorea and epilepsy to warrant its adoption or recommendation to the members of the Neurological Society as a means of cure or as the sole therapeutic measure in such cases.

Dr. Stevens then read a reply to the report of the commission, of which only the outline can be reproduced here. He said that whatever might have been the original condition of the majority of the cases sent to him during the first year, they had long ceased to be cases of functional disease. While, as a matter of fact, all of the patients were incurable with any of the ordinary methods of treatment, and while they had grown worse under such treatment continued during many years, they had in every instance, under his treatment, materially improved in general health and in the diseases for which they were treated. All this improvement had been brought about without recourse to the depressing effects of bromides or the toxic effects of enormous doses of arsenic.

The commission, according to Dr. Stevens, entered upon its work in a manner entirely inconsistent with the true spirit of inquiry. It pursued it in a manner calculated to induce vexation, misunderstanding, and controversy. It occupied many months in securing a few cases, and has never yet complied with its own stipulations. It has through more than two years been occupied in selecting the most unfavorable cases for treat-

ment, and has taken the favorable cases to itself. The spirit of the report is calculated to produce prejudice and to mislead, and the report was made in violation of every principle of right or fairness. The report is represented as an investigation of two diseases, and not of a principle, in direct violation of the pledges of the commission. The commission repeatedly sent cases well known to be unsuitable for the inquiry and contrary to the articles of agreement and the private promises of members, and in this report paraded these cases in long detail with the effect of misleading the judgment of those unacquainted with the facts. It reported the results of treatment of the cases by minimizing the importance of the malady at the beginning of treatment and by magnifying the unfavorable conditions now existing. The results represented are not in conformity with the actual facts, but are grossly at variance with them. It reported as resulting from treatment unfavorable ocular conditions which do not exist, and in this respect made mistakes which should have been avoided.

In the discussion which followed, DR. HAMMOND said that he had seen eight of the cases described, the day before the meeting. The patients and their friends all admitted that the cases had been improved very much by Dr. Stevens' treatment, a fact which was at great variance with the statements made by the same patients to the commission.

DR. SEGUIN said that that part of Dr. Stevens's remarks which reflected upon the fairness and integrity of the commission needed no reply, the names of the members of the commission being a sufficient answer. Dr. Stevens's statements as to the evil effects of the arsenical treatment of chorea and of the bromides in epilepsy were altogether unwarranted by fact.

It was true that the commission had the greatest difficulty in inducing patients to undergo the treatment, but their failure to obtain twelve cases within the first few weeks was not through neglect or violation of the agreement. It was simply an impossibility to supply the necessary material in a given time—enough had been furnished in all. Dr. Stevens, in not furnishing data as to the course and progress of the cases, had violated the compact.

As far as his own cases were concerned, one had been nearly killed by the ocular treatment, which involved the omission of bromides. Another had been under ocular treatment for fifty-two weeks before improvement became marked. Another, a girl with chorea, showed no tangible improvement until after the lapse of seven months. His own experience in cases of chronic chorea, even when of five to seven years' duration, was that they were not merely improved very soon under arsenical treatment with rest in bed, but, as a rule, cured in from two to three months. This girl, though improved under the ocular treatment, had now transient diplopia for far and near, while the second case alluded too saw double on looking to the right. The improvement in these cases (which were the best of the series) could not, therefore be ascribed to the ocular treatment, but was to be attributed to improved health and time. Dr. Stevens had reported fifty per cent. of *cures* of epilepsy in his own (former) series of cases, but in the cases examined by the commission there was not one. Moreover, he had reported his cures taking place in a few weeks after beginning the ocular treatment, while in these cases, where improvement of any kind had taken place, many months had been required before decided change had been manifested.

DR. STARR, in regard to the remarks made by Dr. Hammond, referred to the records of the cases already read to the Society, which demonstrated in each case an increase in the number of attacks, in some of them to three times as many as formerly.

In one case, pronounced by Dr. Webster as normal ophthalmologically, and in every respect a purely functional case, Dr. Stevens claimed to have found optic atrophy, and called it an organic disease.

DR. BIRDSALL had seen one of the epileptics mentioned by Dr. Hammond as having reported improvement to him, and whose sister corroborated the patient's statement. He had asked the sister why she had made this statement. She had replied that she did not refer to the number of fits, which was unchanged, but meant that the patient seemed to be brighter without the bromides. The record showed, however, that the number of attacks had increased, and that the patient was in reality much worse under Dr. Stevens's treatment.

DR. DANA said he had been appointed on the commission by Dr. Stevens himself, and felt that he represented him in a measure, but naturally his chief object had been to obtain the exact truth in the matter. He had sent twelve cases of his own to Dr. Stevens, and had tried hard to get others to go; but he had seen no case much improved under Dr. Stevens's treatment.

DR. STEVENS said that when the investigation was commenced cases were accepted by the commission which ought never to have been taken. One was a pronouncedly organic case, and, in fact, not one of the cases was functional. The operative technique is exceedingly delicate and difficult, and such great skill is required that he himself did not yet claim to have attained perfection; but the more skilful the operator becomes, the more valuable will prove to be this therapeutic measure.

DR. L. C. GRAY did not believe that Dr. Stevens had substantiated his serious charges against the commission or caused any particular improvement in the cases. Esquirol showed in 1828 that temporary improvement took place in all cases of chronic epilepsy in La Salpétrière when treated by drugs known at that day. A decrease of from six to three fits daily could not be considered a permanent improvement, because such decrease was often spontaneous, and in some cases fits spontaneously ceased for years. He agreed with Dr. Seguin, that where improvement did not begin before fifty-two weeks after treatment had been begun, any improvement that might take place could not fairly be ascribed to the measure employed.

DR. SEGUIN said, with reference to the work done by Dr. Stevens, that all of the members of the commission had appreciated it highly, and had felt like adding something commendatory of his skill to the report, but refrained from doing so because, under the circumstances, it might have appeared hypercritical, and was really alien to the subject assigned to the commission, viz., the determination of results.

DR. J. L. CORNING thought that Dr. Dana's tribute to the good work done by Dr. Stevens was in exceedingly good taste. Dr. Stevens's work was unusually scientific

and original, and there seemed to be very little of that sort of work done in New York, where compilation and the importation of foreign ideas were the order of the day. Hence, this discovery of Dr. Stevens ought to meet with wide recognition.

A motion to adopt the report of the commission was then carried by a vote of five to four out of the eighteen members present, the members of the commission refraining from casting their votes.

The following motion, made by Dr. Amidon, was unanimously carried:

"That the thanks of the Society be extended to Dr. Stevens for the assiduous labor he has devoted to the work of the commission, and that the Society assure Dr. Stevens that it highly appreciates the ingenuity and technical skill he has shown in the prosecution of his method."

CORRESPONDENCE.

SNAKE POISON AND ITS ANTIDOTE.

To the Editor of THE MEDICAL NEWS,

SIR: Some dozen people have sent me slips from the western papers as to specifics for snake bites. This nonsense about a remedy which is none at all, is a serious thing, and as some of those who write me are intelligent men, I enclose a note from one whose practical acquaintance with snakes none will dispute. All over our country are to be found, here and there, remedies reputed of value. I tested many, but always failed. I advise some of my too numerous correspondents to re-read my paper. They will find that it answers most of their queries. Very truly yours,

S. WEIR MITCHELL.

The following, one of the many slips spoken of, is taken from the New York *Tribune* of November 7, 1889:

"LOS ANGELES, CAL., Nov. 7.—Hereafter, when camping-out parties are formed, the demijohn full of snake-bite cure will have to be replaced by a bundle of weeds, for T. R. Fisher, an old citizen of Santa Barbara, who is familiar with the habits of the California Indians, claims to have found out their remedy for rattlesnake bites, which is a species of the plant Euphorbia. Dr. S. Weir Mitchell, of Philadelphia, recently stated, in an article which has been copied by the California press, that no specific was known for the virus of the rattlesnake. Mr. Fisher saw this statement and contradicted it, saying that the plant referred to was a sure cure, and he even goes so far as to state that the snakes themselves, when bitten, will make use of the remedy. This receives corroboration from Frank Smith, who lives at Whitewater, in San Bernardino County, on the edge of the Desert. He speaks most of the Indian dialects. The weed, he says, is a Euphorbia, and is common through California and Arizona. It is a vine-like plant, radiating from a centre, growing close to the earth; the leaf resembles the clover, but is less than half as large. When a stem is broken a milky exudation follows, similar to that of the 'milkweed' of the East. Mr. Smith gives this as the method of application: The green weed should be macerated in water, the skin about the bite scarified, and the pulpy mass of the plant placed on it and rubbed well into it; this should be repeated at intervals for fifteen or twenty minutes, and then a poultice of the same plant should be bound on and left. Mr. Smith holds that within forty-eight hours all symptoms of poison will disappear. So confident is he that, in *The Banning Herald*, he offers to settle the discussion with Dr. Mitchell in the Western style, by offering to bet $500 to $1,000 that with the Euphorbia he can cure any case of rattlesnake bite, and he will allow Dr. Mitchell to pick out his own snake. The Mexicans know the weed, and call it Golondrina."

DEPARTMENT OF STATE.
INTERNATIONAL AMERICAN CONFERENCE.
WASHINGTON, November 24, 1889.

DR. S. WEIR MITCHELL,

DEAR SIR: The above is an old story, known to army officers and others for many years. I heard all that was to be said about it in 1869, and so stated in my article "Snake Dance of the Moquis of Arizona."

Surgeon B. J. D. Irwin, U. S. A., has published a monograph on the "Euphorbia Prostrata" ("Golondrina" of the Mexicans, "milkweed" of Americans). It has been used, to my knowledge, by Mexicans and by Pinea and Apache Indians, but it is uncertain in effect and in no sense to be called a sure cure.

I remember an Apache boy who was treated by his own medicine-men; the leg in which the bite was, became paralyzed, atrophied and, I think, ulcerated: boy lived (Old Camp Grant, Arizona, 1870).

Another case, a dog; treated for rattleskake bite in neck; death did not occur for six weeks, but sloughing ulceration began, and ended fatally (Valley of Gila, 1871).

A third case—government mule bitten on muzzle—no benefit at all (Canon of Salt River, December, 1872). In the last instance, Golondrina was mashed up with human urine.

Please excuse my hurried letter, which may or may not contain facts already known to you.

Very truly yours,

JOHN G. BOURKE,
Captain 3d Cavalry,
U. S. Army.

NEWS ITEMS.

Academy of Medicine Election.—The New York Academy of Medicine at its meeting on January 2d elected the following officers: Vice-President, R. C. M. Page; Trustee, Lawrence Johnson; Members of Committee on Admissions, Augustus Caille and Thomas R. French; Member of Committee on Library, Egbert H. Grandin. Dr. W. G. Wylie read a paper on the treatment of surgical peritonitis, which was followed by a discussion.

The Christ Hospital of Cincinnati.—The *Lancet-Clinic* announces the inauguration of a new hospital at Cincinnati with the above title. It will be under the guidance of the Methodist Episcopal Church, but non-sectarian in its charity. This is the second hospital to be founded by that Church in this country, the first one being the Seney Hospital, of Brooklyn. Dr. C. G. Comegys is the senior consultant and chief director in the new Christ's Hospital.

New Appointment.—At a meeting of the Board of Managers of St. Luke's Hospital, New York City, held De-

cember 27, 1889, Dr. T. Halsted Myers was appointed Attending Orthopædic Surgeon to the Hospital.

To Restrict Quackery in Maryland.—At a meeting of the Medical and Chirurgical Faculty of Maryland on January 2d, a bill was framed to be presented to the Legislature for the protection of the people from ignorant and fraudulent practitioners, and for the elevation of the profession in Maryland. The bill provides for a board of twelve medical examiners, nine to be selected from the regular physicians and three from the homœopathists. The appointments are to be made by the Governor; the regulars on the recommendation of a general convention of the schools, and the homœopathists on the recommendation of the State Homœopathic Society. The diploma of a college will not be accepted, and the applicant for license to practise must pass an examination in materia medica, therapeutics, and other branches of medicine. The board shall have the power of revoking the license of physicians given to inebriety, and also of persons advertising to cure special diseases which in the judgment of the board are incurable.

Physicians form a Trust.—It is stated that the doctors of Findlay, Ohio, have formed a "trust," and advanced the price of professional visits from $1 to $1.50 each. The announcement has caused great indignation among the people, as influenza is epidemic. It is charged that the physicians took advantage of the necessity which exists for their services.

Typhus Fever in New York.—Three or four cases of typhus fever have been discovered in the North Brother's Island Hospital of New York City. The infection is believed to have been imported on the steamship "Westernland" by means of the baggage of some German immigrants. An effort will be made to trace the course of each passenger, and their future medical history until the period of typhus incubation shall have expired.

The Presbyterian Hospital of New York.—The recent fire in the north building of the Presbyterian Hospital, New York, has proved a stimulus to the friends of the institution. It is reported that an anonymous donor has promised $250,000 for immediate use if other contributors will subscribe a like amount. The out-patient department of the Hospital, formerly used as a chapel, and the dispensary have been converted into temporary wards, with sixty beds, so that nearly all the former patients can be accommodated.

Obituary.—Dr. Lewis H. Sayre, of New York, the son of Dr. Lewis A. Sayre, died suddenly on January 3d in his thirty-eighth year. Since his graduation from Bellevue Hospital Medical College in 1876 he had been associated with his father in private practice and college work. Death is supposed to have been caused by cardiac disease.

——— Dr. George W. Lawrence, who died at Hot Springs, Arkansas, December 30th, was the senior resident physician of that place. He was born at Plymouth, Pa., in 1823, and graduated from the University of Pennsylvania in 1846. He went to California in 1849, and was on Governor McDougal's surgical staff in 1850. During the late war he became Medical Director in the Confederate service, and occupied other responsible offices until June, 1865. His residence at Hot Springs dates from 1859. His early life was eventful and somewhat adventurous, while his later years were replete with responsibilities and many well-earned favors.

——— Dr. Brehmer, of the well-known Sanitarium for Consumptives at Göbersdorf, died on the 22d ult., from inflammation of the lungs, following a cold caught during a Christmas shopping trip to Breslau. In all probability he was a victim to the prevalent epidemic.

Post-graduate Instruction in London.—The clinical course of instruction for graduates begins its first term on January 13, Dr. Octavius Sturges opening it at the Great Ormond Street Hospital on the acute lung affections of infancy. Among the other physicians who will teach in this first course, are Drs. Bastian, Barlow, Buzzard, Beevor, J. K. Fowler, Gowers, T. H. Green, Hadden, Kidd, Angel Money, Ormerod, J. F. Payne, F. T. Roberts and C. Theodore Willians. On the surgical staff there will be Mr. Jonathan Hutchinson, president of the organization, and Messrs. Brudenell Carter, Marcus Gunn, Victor Horsley, W. Lang, J. H. Morgan, Edmund Owen, Bernard Pitts and A. Q. Silcock. Dr. J. Fletcher Little, Cavendish Square, is the secretary. The fee will be nine guineas for a course of seventy lectures, extending over a period of nine weeks.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 30, 1889, TO JANUARY 6, 1890.

By direction of the Secretary of War, the leave of absence granted E. A. Mearns, *Captain and Assistant Surgeon*, in S. O. 244, October 19, 1889, from this office, is extended two months.—*S. O. 303, A. G. O.*, December 30, 1889.

By direction of the Secretary of War, Par. 1, S. O. 180, Department of the Missouri, December 6, 1889, transferring Nathan S. Jarvis, *First Lieutenant and Assistant Surgeon*, from Fort Lewis, Colorado, to Camp Wade, Kingfisher, Indian Territory, is confirmed.—Par. 6, *S. O. 303, A. G. O.*, December 30, 1889.

By direction of the Secretary of War, the leave of absence granted Julian M. Cabell, *First Lieutenant and Assistant Surgeon*, in S. O. 249, A. G. O., October 25, is extended one month.—*S. O. 304, A. G. O.*, December 31, 1889.

By direction of the Secretary of War, ordinary leave of absence for two months is granted Junius L. Powell, *Captain and Assistant Surgeon*, in extension of the leave of absence on account of sickness, granted him in S. O. 258, November 5, 1889, from this office.—Par. 1, *S. O. 1, A. G. O.*, January 2, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING JANUARY 4, 1890.

Clark, John H., *Medical Inspector.*—Ordered to the U. S. S. "Baltimore."

Diehl, Oliver, *Passed Assistant Surgeon.*—Ordered to the U. S. S. "Baltimore."

Stitt, E. R., *Assistant Surgeon.*—Ordered to the U. S. S. "Baltimore."

Smith, Howard, *Surgeon.*—Ordered to the U. S. S. "Alliance."

Gatewood, J. D., *Passed Assistant Surgeon.*—Ordered to the U. S. S. "Despatch."

Tryon, J. R., *Surgeon.*—Ordered to the Naval Medical Examining Board.

Scofield, W. K., *Medical Inspector.*—Ordered to special duty at New York City.

Guiteras, D. M., *Passed Assistant Surgeon.*—Ordered to the Naval Hospital, Philadelphia, Pa.

ORIGINAL LECTURES.

THE TREATMENT OF PNEUMONIA BY VERATRUM VIRIDE AND DIGITALIS.

Abstract of a Lecture
Delivered at the University of Pennsylvania,

BY H. C. WOOD, M.D., LL.D.,
PROFESSOR OF THERAPEUTICS.

PASSING from the subject of digitalis in cases of heart disease, let me call your attention, gentlemen, to its use in some cases of acute disease. Just as in heart disease failing heart-power is a positive indication of the necessity for the use of digitalis, so in acute disease failing heart-power is a reason for its use. In order that you may better understand the principles that govern your employment of the drug in cases of acute heart-failure, let me take the subject of pneumonia. It is unnecessary for me to refer to the symptoms in detail, and I will do so only so far as to enable you to apply the principle to diseases of that class. In order better to understand the use of this drug in pneumonia, it seems to be essential that you should have knowledge of the use of drugs whose effect is the opposite of that of digitalis; I therefore ask your pardon for bringing forward here certain general facts in regard to drugs which are not cardiac stimulants, but are cardiac sedatives. Let us suppose that we have a drug which is a powerful cardiac sedative, which is the opposite of digitalis, and which is also a powerful vascular sedative, causing dilatation of the bloodvessels. Such a drug we find in veratrum viride.

Now we take a case of ordinary pneumonia. We are called to it in the very flush of the disease. We find that the chill has passed by, that the patient has a high fever, that there is a high, bounding pulse, full and strong. We notice, also, that the lower lobe over the left lung is full of blood. What has brought the flux of blood to that point? There has been everywhere in the lower lobe of that lung a dilatation of capillaries, a vacuum, the effect of a relaxation of pressure. The heart being excited and the arterial pressure being continued, these relaxed, dilated vessels draw the blood into them, the whole lobe becomes full of blood, while the arterial or capillary system everywhere is contracted save only in this lobe over the lung. Under such circumstances digitalis is to be used. In the first place, it depresses and quiets the heart, it reduces the arterial pressure and drives the blood into that territory where resistance to blood entrance is slight. But it does more than this. It builds up the capillaries all through the system. You will remember that the relaxed vessels of the abdomen are of such size that they are capable of holding all the blood in the body. You can put all the blood of a man, after death, in his abdominal vessels, and they will not be over full. Now when, under the influence of a dose of veratrum, the heart has been lowered in power and the whole abdominal cavity has been opened wide, there is then a great suction of blood away from this lung. The blood that fills and chokes up this territory goes off to the abdomen, and you thus get an effect which, in days gone by, our ancestors got by the use of the lancet. You bleed a man, not into a bowl, but you bleed him into his own abdomen; and after the danger has passed by, you have not taken power from the general system. You depress, but you do not exhaust, the patient. Thus, in pneumonia, the period comes when power is needed to support the disease; it does not find the patient wholly exhausted by reason of the bleeding, but by the use of veratrum the functional activity returns. Bear in mind that depression is not exhaustion—that depression is the strong man's safeguard, that exhaustion is the strong man's danger. In pneumonia, therefore, if you have this condition of depression from veratrum early in the attack, you have reduced the congestion and possibly limited the force of the disease. But let the case go along. By and by a time comes when half, or a third, or perhaps the whole of one lung is consolidated. What does that mean? Suppose that we have a pair of lungs each of which is full of capillaries, the cavity between them affording a channel of communication between the right and left sides of the heart. We will say that in the upper part of the left lung there is a channel of communication, which is represented by 100, and in the lower lobe one of the same size, and again one in the right lung. Thus there is normally a cavity or a channel, represented by "400," through which the blood flows from the right to the left side of the heart. There comes an outpouring of plasma; all these capillaries are pressed upon—practically they are obliterated; and if a whole lung is obliterated, as sometimes happens, there is only half-communication between the right and left sides of the heart. Do you not see that, under these circumstances, the right side of the heart is placed under a perpetual strain, and that the strain increases all the time, from a little failure at this moment to throw back a little blood into the venous system and at the next moment a little failure to throw an increase of blood to the venous system? By and by the pressure is all on the right side of the heart, and the patient dies. Under these circumstances you have the right side of the heart becoming angry, though impotent in its rage, acting spasmodically and in every possible way except the right and proper way. You give a full dose of the digitalis, and continue its use until you have some evidence of its presence. The effect will be that the right side of the heart will begin to beat slowly and with long pauses. There is a driving force behind the blood, which throws it through this narrow channel, fills up that left ventricle and restores the balance of the circulation. You cannot do this with any remedy so well as you can do it with digitalis. It is more powerful than any other, though slow in action. Alcohol does not do this. Alcohol is a

stimulant of the general system. It has some power over the heart, but it is a power that is a weakness as compared with the power of digitalis. Therefore, in advanced pneumonia there is no remedy that will take the place of this drug. But bear in mind that you have to give it in sufficient doses to produce an effect. If you are afraid of it, if you give it homœopathically, if you merely rub the back of the patient's neck with the bottle, the disease will hold its own. Here, as in all cases where you are using digitalis fully and freely, you watch the pulse, and will remember that its influence is to determine your treatment. Having given the digitalis, you may find, at eight o'clock in the morning, when you visit the patient, that you have a distinct digitalis pulse; then you will wait until three o'clock, or perhaps until six o'clock, and, if you find that your digitalis pulse is losing, you will throw in your dose of digitalis—your doses being guided always by the pulse.

Digitalis is useful in advanced stages of typhoid fever, when the pulse fails. It is useful in any acute disease when the pulse fails. But remember always that experiments have shown that a very high temperature renders the system less susceptible to the action of digitalis. It is not true that digitalis will not act when the temperature is up. I have over and over again seen it act with great power in cases in which the temperature was 105°. This high temperature simply makes the heart more rebellious; it does not suspend the activity of the digitalis.

In acute syncope digitalis is of value. Recollect, however, that it is very slow in its action—that in order to get any effect from it you must give it hypodermically.

EXTREME BLOOD-PRESSURES.

Notes from the Clinics of Dr. S. Weir Mitchell at the Infirmary for Nervous Diseases of the Orthopædic Hospital.

[Reported by Guy Hinsdale, M.D.]

The interesting case which I present to you to-day I bring before you chiefly for the purpose of calling your attention to its peculiarities, some of which may have escaped your notice. I do not purpose dwelling on them for the length of time I would give to them in a lecture, but simply to call your attention to the facts before us. For example, here is the case of Mr. B. G., aged forty-one, who is suffering from paralysis of the right side of the body, with aphasia, due, I think, to the occlusion of an artery in the left side of the brain. I do not intend to go into the details of the case, but I will state that he has had albumin and granular casts in his urine for more than a year, although he has never suffered in any other way up to January 9, 1888.

At twelve o'clock of that night he had the attack of hemiplegia of which I have just spoken. He was unconscious for two days, but does not think that he was convulsed. The urine was drawn for three weeks. After the fourth week he was able to walk, and gradually regained power both in the legs and arms. The dynamometer showed 90 on the right side and 95 on the left. There was no disturbance of sensation or of intelligence. There were no hallucinations, and he slept well. There was no vertigo. The speech was slow. Station fair. Knee-jerk ++ on both sides; reinforcement normal. He hesitated in speech and failed to find some words, although he could get the desired word after a good deal of effort. There was a slight apex systolic murmur.

The disks of both eyes were very cloudy on the edges and somewhat swollen—the left more than the right. The central veins were fuller than normal. There were large quantities of albumin in the urine, and a considerable amount of granular casts at all times. The patient, however, is very much better than when he entered our wards. He walks better and is less irritable. There is at present just a trace of albumin in his urine.

I have omitted his skimmed milk at present (for he takes nothing else), that you may see the condition to which I desire to call your attention. I have also had the iron stopped for three or four days. He now shows to an imperfect degree what he showed to excess when he entered the hospital. As you will observe, on the right side of the head the temporal artery is large and remarkably serpentine. If you compress its course to absolute obliteration of the blood-flow, it continues to pulsate beyond the point of pressure; moreover, it pulsates strongly. This must, of course, be due to the fact that, owing to the great intravascular pressure, the anastomosing vessels below the point compressed convey to ultimate branches of the temporal the cardiac impulse, and perhaps, too, all are dilated, as the temporals are most certainly.

It is not a little singular that, after the first few days of treatment, this symptom, having disappeared on the right side, became distinctly visible on the left. If you examine the pulsations in the arteries at the wrist you will find that they, too, are full, strong, and difficult to obliterate; but when pressed upon so as absolutely to stop the blood-current, we do not see the same phenomenon as in the temporals, where it is obvious even to a careless observer. When, two years ago, I first saw this phenomenon, it interested me greatly, as this evidence of very high tension is rarely found, except in very old people with diseased arteries, or in certain cases of Bright's disease. The case before you illustrates it admirably.

Without remarking further upon this special example, I desire to call your attention to one as interesting. The patient some of you saw last year. He is a merchant from New England, aged thirty-eight, who came here complaining of intense pain in the head. These headaches were so violent as to make it necessary for him to remain in bed for several days at a time. They had been attributed to different causes, but, strangely enough, never to the right one, until he came hither in March, 1887.

The man was tall—six feet two inches in height—and extremely pallid. The blood-corpuscles, which were counted by Dr. J. K. Mitchell, were 4,100,000 per c. mm. and the hæmoglobin 95 per cent. The urine was clear and pale. Sp. gr. 1012, with abundant albumin and epithelia of yellowish tint. There were uric acid, some blood-clots, much granular matter and numerous casts.

The heart was large and irregular in action. There was a strong apex systolic murmur heard around under the left shoulder.

Dr. de Schweinitz made careful examinations of the eyes. His statement, which I append below, shows the remarkable changes in this interesting case. The tension in the temporals exceeded anything I have ever seen.

It was difficult to compress them, and when we did so the throb beyond the point of pressure was almost as great as though no interruption had been made to the arterial current. At first it was possible to feel pulsations when, with the compressing fingers above and below, two inches apart, we sought between them the evidence of continued pressure. You could notice in this case, as in the one last related, the enormous amount of tortuosity, the left artery sometimes exceeding the right as to this, or, again, the right being the larger and more crooked. The tension in the radials was also the greatest I have ever met with. It was difficult for me to understand how, with so much pressure, it was possible for life to go on and for vessels to remain unruptured. This is the only case in which I found it impossible to stop pulsation in the radial beyond the finger, after all circulation had been locally obliterated by pressure. Since then I have seen it twice. This phenomenon was not as marked as in the temporals, but it was sufficiently apparent to anyone.

This sign of high tension is a somewhat valuable symptom, because it disappears with great readiness under certain treatment; and this fall of pressure is an excellent indication of improvement on the part of the patient. I may as well say to you here that in nearly all the cases of very high tension with renal disease, there is also retinal trouble—at least it has so appeared to me. While this tension is thus greatly increased beyond the normal blood pressure, it is usually capable of being more or less controlled by a number of means; thus, in the last case mentioned, the individual having been put on a diet of skimmed milk alone, the tension in the radials fell from 600 of an arbitrary scale to 450 within a week. When to this there were added thirty-five drops of the tincture of the chloride of iron, four times a day, with an increased amount of milk, another week brought the tension down to one-half of what it was at the beginning of this diet. The headaches rapidly improved and the sluggish condition of the extremities disappeared.

Finally, his eyes to a large extent recovered their power of vision, as to which I leave Dr. de Schweinitz's notes to tell. It was, however, a hopeless case and has since died, but life was undoubtedly prolonged for more than a year, and he escaped great suffering. He was enabled, also, for a time to go back into active business and to take such care of his large affairs as was necessary for the future protection of his family. He lived on milk for many months and took tincture of the chloride of iron in doses of half an ounce a day.

Examination of eyes by Dr. de Schweinitz:

January 22, 1887. R. E. vision equals $\frac{1}{6}$ of normal. L. E. vision equals $\frac{1}{1}$ of normal. Extensive albuminuric retinitis. Enormous swelling of the optic disks. In the R. E. 1.12 mm.; L. E. 1.00 mm.

February 14, 1887. R. E. vision equals $\frac{1}{4}$ of normal; L. E. $\frac{1}{4}$ and part of $\frac{1}{3}$ normal.

March 23, 1887. Vision in the R. E. equals $\frac{1}{2}$ of normal; the summit of the disk still unchanged. L. E. vision $\frac{1}{2}$ of normal, with part of $\frac{2}{3}$ of normal; disk distinctly less swollen—0.92 mm.

April 13, 1887. Vision in the R. E. $\frac{1}{2}$ of normal, and swelling of the disk 0.92 mm. Vision in the L. E. $\frac{2}{3}$ of normal; swelling of the disk 0.85 mm.

The chief changes observed from his first visit, January 22, 1887, to his last visit, May 31, 1887, were a gradual lessening in the size and extent of the infiltrated optic disk, causing the diminution in elevation noted above; the clearing up of the retinal infiltration in the neighborhood of the macula causing the improvement in direct vision, which, at the beginning, was only $\frac{1}{6}$ of normal; but at the last visit was full $\frac{2}{3}$ of normal. No special changes were noted in the vessels of the retina, except that as the infiltration lessened, outlines previously hidden became visible.

In conclusion, I desire to add, in brief shape, the case of L. P., aged twenty-six years, clerk. He presented all the signs of advanced Bright's disease—enormous tension, great œdema, diseased heart, and total blindness. I have mislaid Dr. Dyer's notes of the eye-changes. My own records state that his eye-ground was disfigured with hemorrhages, old and new; and he was unable to go about the streets alone, as he could barely distinguish day from night. Tinct. ferri chlor. had been used up to one ounce a day, with no relief.

Under diet without meats or eggs, and seven drachms a day of tinct. ferri chlor., he regained sight so as to be able to keep books for several months, and supposed himself well; but, as usual, at last the symptoms returned. The sight, however, remained good up to death, two years later.

In one of the hospital cases I used nitrous ether alone, and then other iron salts, but got no such results as from old tinctures of iron. Of course, tincture of iron has been much used in these cases, but perhaps not in heroic doses.

The ether present in tincture of iron is usually held to be responsible for some of its effects. Mr. Frank E. Morgan has been kind enough to distil for me an old tincture of the chloride. He obtained early an ounce of ether from one pint of tincture. The amount is so small that it seems difficult to see how the fraction of it in sixty grain doses of tincture could be a powerful agent. It did not seem to be such when used apart from iron.

The process was conducted very carefully, the distillate being collected in fractions and identified. At no time, either by physical or chemical tests, could any ether be found other than nitrous ether. Mr. Morgan writes that while it is claimed that very minute quantities of other ether or ethers are at times present, he has not found any positive statement as to their character. He adds, that from the fact that an excess of hydrochloric acid is used in preparing the tincture, it is often inferred that ethyl chloride or hydrochloric ether is present, but as this ether is formed with difficulty, and perhaps only in presence of free chlorine, it is extremely doubtful.

I used this ether in twenty to thirty minim doses in the cases of excessive blood-pressure with little effect. With the practical results of the treatment of these cases I am well pleased, but it seems to me that we are left without an explanation of the facts. It is generally accepted as true that the salts of iron raise the blood-pressure; as regards abnormal pressures in renal disease the reverse is correct for perchloride of iron in alcoholic solution. Whether other astringent ferric salts act in like manner I do not yet know, nor is it quite clear how the lowering of pressure is effected, but of its amount and permanence you have been able to judge.

THE PRESENT EPIDEMIC OF INFLUENZA.

A Clinical Lecture delivered at the Pennsylvania Hospital, January 11, 1890,

By J. M. Da COSTA, M.D., LL.D.

[Reported by William H. Morrison, M.D.]

Gentlemen: The occurrence in our midst of an epidemic of catarrhal fever or influenza, and the fact that we have had a large number of cases of this disease in our wards, have suggested the propriety of giving you a lecture on the subject, in which the prominent groups of the disease might be laid before you, and which would serve to illustrate not simply a single case, but the varieties of this strange malady.

It is not my purpose to treat the subject historically, but rather to view it clinically. I have myself passed through more than one epidemic of catarrhal fever, and can claim familiarity with its symptoms; and comparing what I have seen in previous epidemics with what I have found in this, I shall be able, as I proceed, to point out how the present epidemic differs from those of previous years.

This widespread malady, which has committed such havoc on the Continent of Europe, and which has proven itself here, in the last month, so destructive to comfort and so perilous in its secondary consequences, is of uncertain origin. It comes; it goes. It comes without warning; it disappears, leaving behind it sporadic cases, but speedily loses all trace of its epidemic form. As I have told you, however, I propose to treat the subject from a clinical standpoint, rather than view it pathologically or in its broad general aspects. I shall, therefore, introduce my subject by showing you a few cases which illustrate different types of the malady.

Case I.—This man, a German, was admitted to the hospital January 9, 1890. His family history is good. He does not drink, and has had no severe disease. Eleven years ago he had some kind of fever, but has not been ill since then. The present illness began abruptly, December 25th, with chilly feelings up and down the spine, followed by headache and some cough, which occurred in paroxysms, and was especially severe in the evening. There was no expectoration. He had a general sore feeling. There was slight constipation, and soreness over the abdomen, which was thought to be due to the cough. The eyes and nose discharged freely. He consulted a physician, and in a day or two improved; all the time he continued at work. January 6th he began to show signs of a relapse. All his previous symptoms returned with great severity, and he became so weak that he could not stand. On admission into the hospital he had cough, a sore feeling all over, the eyes discharged freely, the temperature was 99°, pulse 76, and respiration 28. A few bronchial râles could be detected. The tongue was tremulous, flabby, and slightly coated. The knee-jerk was present; the urine was of a dark amber color, specific gravity 1034; no albumin.

Examining him this morning we find that the tongue is covered with a white coat. He still has watery eyes and cough; the temperature is 98°; he has harsh respiration at the base of the left chest; at the lower part of the right chest posteriorly the respiratory murmur is feeble, and on percussion the resonance is not so great as on the left side. We find the same signs anteriorly. There is, therefore, some congestion of the lower part of the right lung. The heart sounds are normal so far as murmur is concerned, but the first sound is rather feeble, which corresponds with the very compressible state of the pulse. The bowels still tend to constipation. He does not perspire except after the paroxysms of coughing.

Case II.—This man is thirty-three years of age. The present attack began two weeks ago with dizziness, some vomiting, and cough. The bowels were constipated. There was sore throat and coryza. Although a strong, robust man, he rapidly grew very weak. There was profuse sweating after coughing. There was no special shortness of breath. There was general soreness, with a great deal of pain in the bones, especially at the wrists; none in the spine. The great debility was the most marked symptom in this case, and was the more noticeable on account of the former condition of the man. A few days ago he had repeated chills and tremulousness of the hands. The constipation has, in the last day or two, been succeeded by diarrhœa. When admitted, the temperature was 98°, the pulse 76, and the respirations 20. The patellar tendon reflex was present. The urine was dark, with a specific gravity of 1030, of acid reaction and contained a trace of albumin, which still persists. It is but fair to state in this connection that the man has been a free liver. He also showed signs of a good deal of catarrh. The eyes were watery. Coryza existed in the early part of the attack, with considerable sneezing.

He is still very weak. This morning the temperature is 98.4°; the pulse is 60 per minute and is extremely weak; it is absolutely thready. The first sound of the heart is so feeble that it can barely be detected. This is very much like the heart we get in an advanced stage of typhoid fever, barring, however, the difference in rapidity. Here the heart is slow, while in typhoid fever it is usually rapid. There is no murmur, but a distinct, sharp second sound. There is harsh respiration on the left side, and some impairment of resonance below the area of harsh respiration, showing congestion. Râles were noticed, but I do not hear them this morning. The splenic dulness extends just to the margin of the ribs. The hepatic dulness is normal.

In the way of treatment he has received for the throat a gargle of salicylate of sodium with glycerin and water. He has taken twelve grains of quinine a day, and a mixture containing muriate of ammonium. This cough mixture need now be given only occasionally, and we shall order him four ounces of whiskey a day and one one-hundredth of a grain of strychnine every fourth hour. He will also have turpentine stupes applied to the back of the chest, especially on the left side.

There are so many cases of this malady in the hospital that, in one clinic, I could hardly exhaust them. But I will show you one more case, which is of great therapeutic interest.

Case III.—This man is twenty-six years of age, and has been in the hospital since December 26th. When admitted, his temperature was 100°, his pulse 88, and his respiration 34 per minute. His eyes were injected and his tongue coated. His heart's action was weak, and there was noticed reduplication of the first sound and a faint systolic mitral murmur. The man was very weak. The lungs were normal, with the exception of a few

mucous râles. His symptoms were those of such prostration that he was thought to be in the so-called typhoid condition, and the opinion was entertained that it might possibly be a case of latent typhoid fever. Indeed, he was so drowsy that we could not get any account of his illness, and this added much to the difficulty. Watching the man, we found that there was not the least evidence of typhoid fever. There were no spots, no diarrhœa, and the splenic dulness extended only slightly below the margin of the ribs. The peculiarity of this case is that while, almost from the beginning, the temperature has been between 98° and 99°, and the pulse extremely feeble, he was dull, his pupils somewhat dilated, and he was extremely delirious. He could not sleep at night, and the only sleep obtained was by the use of small doses of chloral. This, with the prostrated condition, suggested the possibility of typhoid fever. As his mental condition improved, it became clear that this was not the case. He told us that he had had symptoms of coryza, pain in the bones, and all the symptoms of the prevailing epidemic.

Let us see what his condition is to-day. He, too, has a weak first sound, but not so weak as in the preceding case. He has a compressible pulse, moderately weak. The lungs are clearer. He has had no cough since admission and the mind is clear. I think that this is an undoubted case of influenza.

What I desire particularly to call your attention to is the violent and persistent delirium which was present, and the manner in which it was relieved. When I first saw the man I was struck with the sluggish, dilated pupil; the feeble pulse, and the extreme delirium, with a temperature which was normal or slightly subnormal. It at once occurred to me that here was a case of delirium from inanition. This I have seen more than once at the end of an attack of typhoid fever, or any other depressing disorder interfering with nutrition, such as cancer of the stomach, where the brain is disturbed because it does not get a proper amount of stimulus of blood. I had the man placed on liberal supply of food given at short intervals and associated with stimulants, and in twenty-four hours the delirium had passed away. It was clearly a case of delirium from inanition. Do not misunderstand me. Do not suppose that this is a specific delirium. As I have said, I have seen this delirium in other typhoid conditions, using this term in a wide sense, as a result of the brain being illy supplied with its proper stimulation of blood. The man is now convalescent, and simply requires a chalybeate tonic. We shall give him five grains of tartrate of iron and potassium three times daily. The stimulation with a liberal supply of food will be continued.

Leaving these cases, I shall make some general remarks upon this disease, to which, for some absurd reason, we have applied the French name "la grippe," which means nothing so far as the disease is concerned. Influenza or catarrhal fever, as is illustrated by these cases and many others that I have lately seen, almost invariably begins acutely. Nearly all of the cases that I have met with started suddenly in persons previously in good health. One case came under my notice where a physician was so abruptly seized with pain in the back that he had to lie down on a bed, and with difficulty could leave the house. In other instances, not quite so marked, the severity of the pain in the back has been great and has been the first manifestation of the disease. The pain is often referred to the middle of the back in the dorsal region, and it is quite commonly observed that starting in this position it spreads downward into the legs. As described to me, the pain is at times sharp, with a dull pain persisting. The patient is never free from pain, which occasionally rises into acute exacerbations. While many of the cases begin with pain in the back, they soon have pain in the bones followed by headache and moderate fever, and then there are or are not catarrhal symptoms.

I have partly traced the development of the disease in these patients; let us now pay some attention to the character of the fever with which these painful sensations soon become associated. In the majority of instances the fever is moderate and lasts about three or four days. The fever is at its height in from twenty-four to thirty-six hours; then it slowly subsides, and the temperature may go below normal. In one case, it passed to 96° and there was profuse sweating, something like a crisis taking place. During the period of highest temperature lasting thirty-six or possibly forty-eight hours, there is only the ordinary variation of about one degree between the morning and evening temperatures. There is really a slight continued fever, and not a fever with remissions and exacerbations as in malarial fever. As a rule, the temperature does not exceed 103°; but, by way of variety, I have in this epidemic encountered a few cases in which the temperature at the onset unexpectedly shot up to 105° and the next day went down to about 100°, and then the case ran the ordinary course, terminating in recovery. In two of these cases bloody sputum or pure blood was at first expectorated.

With the fever we have the ordinary concomitants; high colored urine of a high specific gravity, without albumin. In one of the cases before you there is a trace of albumin in the urine, but as the man is of rather intemperate habits, it is a question whether it does not belong to the individual rather than to the disease.

Another peculiarity about the disease is the occurrence of catarrhal symptoms in the eyes and nose with cough, which is frequently laryngeal rather than bronchial. These catarrhal symptoms are, however, often absent. Some of the worst cases that I have seen have had no catarrhal symptoms whatever in the eyes, throat, or anywhere else. When the catarrhal symptoms are present they are more apt to involve the eyes, nose, throat, and larynx, than the bronchial tubes, although a fair proportion of cases have catarrhal bronchial râles, and some have even congestion of the lungs, as illustrated by the cases before you. In a few instances epistaxis comes on, and with the occurrence of high fever and debility you are irresistibly made to think of beginning typhoid.

One of the most singular features of the present epidemic is the prevalence of the nervous symptoms. As I have stated, I have passed through other epidemics of catarrhal fever, but this one seems to be stamped by the prominence of the nervous symptoms. These are shown by the violent headache, the severe pain all over the body, the pain in the spine travelling downward, and also by what I have seen in quite a number of cases, hyperæsthesia or general sensitiveness of the surface. This is something more than what might be attributed to the efforts of coughing. Then, too, in some of the

cases, there is delirium, not simply the delirium of inanition, as occurred in one of the cases before you, but a delirium with violent headache, this delirium sometimes taking strange forms. In one case, that of a most refined lady, who when well would hardly recognize an oath, when she became delirious from an attack of influenza, swore at her doctor every time he entered the room. I have been told of instances in which patients have lost their minds from the violence of the headache and the delirium. Besides the delirium, there are in some cases convulsions. About a week ago, I was called by Dr. Rosenthal to see a young man who, while in perfect health, was seized with violent headache, severe pain in the back, pain in the limbs, slight catarrhal symptoms, considerable congestion of the lungs, but no pneumonia. Almost from the onset he had spasms in the arms.

The spasms were most marked in the left arm, although the right was also affected. He was very restless, and slightly delirious, but not markedly so. His temperature, almost from the beginning, was 97°. I found him with pupils somewhat dilated and head slightly rigid, and the presence of cerebro-spinal fever at once suggested itself; but further investigation showed that this was not the case. There was no eruption; the spasms were limited to the arms; there was congestion of the lungs; and, above all, there was no fever, the temperature remaining about 97°. The only thing that gave any relief from the spasms was chloral. Notwithstanding the fact that atropine and opium were used hypodermically this patient gradually sank under the violence of the disease. I know of one case in which paralysis of the lower extremities has followed influenza. It is slowly yielding, and the patient will recover. This case had a marked history of a preceding attack of influenza. I know of several others in which convulsions occurred. The kind of cases I have just mentioned have probably given rise to the idea with some that cerebro-spinal fever and influenza are the same disease. The prostrating influence of the malady on the nervous system is also shown by the fact that patients often stagger on getting out of bed. A prominent lawyer whom I recently attended, thinking that, as he was compelled to remain in the house, it would be a good time to get up his work, sent for his papers, but a few minutes' attempt cured him of this idea and he was glad to lie down. This debility remains for a long time, and is often associated with considerable sweating. The pains often remain, and do not necessarily pass away on the subsidence of the rather short fever. In some cases profuse and persistent sweating is also very common during convalescence, and the patient looks anæmic and miserable. I have seen the knee-jerk absent at the height of the malady, but in the majority it is preserved. Cramps in both calves and shoulders, as well as in the chest muscles, have been reported to me by a physician as happening after the febrile stage had passed.

The main *complication* of ordinary catarrhal fever is, as you know, pneumonia, or what is called pneumonia. Looking over the records of boards of health of different cities, it will be found that the deaths from pneumonia have nearly doubled. What is called pneumonia must therefore be set down as one of the chief complications. You notice that I say "what is called pneumonia." A great many of these cases are simply heavily congested lungs, with great debility, the lungs seeming to collapse. There does not seem to be a true process of pneumonic exudation. While in many cases there is slight dulness on percussion, yet it is not absolute, and the high-pitched bronchial breathing of croupous pneumonia is found in only a few instances. There is no consolidation. This has been the characteristic in most of the cases that we call pneumonia. It is probably proper to speak of these cases as pneumonia, but I want you to bear in mind the difference between this condition and ordinary croupous pneumonia.

Let me call attention to another peculiarity that I have noticed in a large number of instances. A great many persons when seized, and often during the height of the attack, complain of violent pain in the left side, but I have not found any friction sounds, save in one instance, and this may have been accidental. There is want of expansion of the lower part of the lung, usually on the left side, associated with this violent and persistent pain, which makes the patient think that he has pneumonia or some other grave condition of the lung.

We know nothing of the cause of this disease. It is epidemic, and I think myself that it is feebly contagious. It would be an admirable thing if some of our over-filled treasury could flow into the channels of science, and that a commission be appointed to investigate this disease bacteriologically and chemically. We accept the microbic nature of its origin, but it has not been proven.

The prognosis is favorable, but the general mortality is increased by the epidemic. This is because persons previously diseased are carried off. For instance, in these two cases with feeble heart, if any unusual exertion were made the patients would probably die. If an elderly person with fatty heart contracts this disease, for it is no respector of age, he would be in imminent danger. We call this heart failure, but these hearts are diseased and enfeebled still more by the malady. In the two cases before you, I think from the previous condition of the patients and their age that there was no feeble heart prior to the present illness.

I have mentioned relapse. I have seen few distinct examples of this. One was that of a lady who had her first attack in the country and came to town to break it up. She was well for two weeks when she was attacked the second time. Another case was that of a gentleman who was suddenly seized with the relapse while in church, two weeks after the first attack. In a third case pneumonia occurred in the relapse. The longest interval I have known was two weeks, the shortest five days. To prevent relapse, great care is necessary in not going back to work too soon, and not exposing one's self to wet and cold, and with this there should be a judicious use of tonics, and even of stimulants.

Now, a few words in conclusion with reference to the treatment. The treatment must, of course, be the ordinary treatment of catarrhal affections. For the relaxed and irritated throat I have found nothing so serviceable as a gargle of salicylate of sodium, glycerin, and water. For the nasal catarrh, which at times is very unpleasant, I have found that a two per cent. solution of cocaine does the most good. The bronchial catarrh should be treated as any other bronchial catarrh, according to the exact seat and the number of râles. A good deal of the paroxysmal cough is laryngeal, and you will find that small doses of opium at night, or bromide and

opium, or what I have employed in a number of cases, broken doses of Dover's powder, will give good results. One-fourth of a grain of codeine, repeated according to the circumstances of the case, is often useful; it allays the cough, induces sleep, and does not cause much sweating. Let me say here, that while perhaps the routine practice of using diaphoretics in these cases is useful, yet such drugs must be used with judgment. In some cases there is a great tendency to sweating, and you do not want to increase it, as it rather adds to the debility. The diaphoretic must be adapted to the individual case, not employed too actively, and not at all where sweating is a prominent symptom.

The debility must be borne in mind, and it is good practice to give sulphate of cinchonidine or quinine, ten or twelve grains daily. Nourishment should be kept up, and the action of the bowels looked after. The patient should not be overpurged, for, in some instances, diarrhœa is associated with the malady.

For the headache and the pain in the bones I have found two remedies of especial advantage. One is antipyrin in five-grain doses, with a grain or two of quinine to prevent depression, repeated every two or three hours until the headache is relieved; the other is phenacetin in five-grain doses. In one instance where these two drugs failed to relieve the headache I found gelsemium to answer.

The general strength and the circulation must be looked after, and especially during convalescence the patient must receive nutritious food, alcohol, small doses of strychnine, and, later, iron.

I shall not speak of the treatment of the complication pneumonia, but let me point out, in concluding these remarks, that you should keep your patients for a long time on tonics which may prevent relapse, and, indeed, it may be a question whether it would not be advisable when the disease makes its appearance in a household to place the whole family on the use of tonics, such as cinchonidine or quinine, as a preventive. My experience is that while this will not ward off the disease, it renders the attack less severe.

I have made these cases an opportunity to lecture to you upon the prevailing epidemic, and I trust that the illustrations that I have given will serve to enforce the lessons laid down and leave a clear picture of the affection upon your minds.

ORIGINAL ARTICLES.

ON THE CHOICE OF METHODS IN THE TREATMENT OF UTERINE CANCER.

BY REEVES JACKSON, A.M., M.D.,
PROFESSOR OF GYNECOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS OF CHICAGO, ETC.

IT is now very generally believed that cancer of the uterus is a local disease, and that at some stage of its existence it may be permanently removed. Likewise, it is understood that the curable period in the history of the disease is usually a very early one, and that the most favorable time for operative measures has very frequently passed before the presence of the disease is known or its nature recognized. Equally true with these propositions is a third—namely, that in order to effect a permanent cure the removal of the disease must be complete. If any portion be permitted to remain, recurrence will surely manifest itself.

The modern methods by which the removal of uterine cancer is essayed are chiefly three in number, as follows:

1. Amputation or excision of the diseased structures by knife, scissors, or curette.
2. Actual or chemical cauterization.
3. Extirpation of the entire uterus.

The first and second of these methods may, of course, be variously combined.

I desire to discuss and compare these plans with the view of determining the question: which of them should be preferred for the radical treatment of cancer of the uterus?

If the theory of local origin and limitation upon which all of these methods are based be true, it would seem unimportant, so far as permanency of result is concerned, which method be chosen, the only essential factor being thoroughness of removal; and the operator might feel at liberty to choose the method which sufficiently abundant experience may have shown to be the safer in immediate result. And why not?

For various reasons known to themselves certain operators have given preference apparently to one of the above mentioned methods, and adopted it to the entire or comparative exclusion of the others: and, as a result, we are now in possession of a sufficiently large number of observations, extending over a sufficient length of time to enable us, with a fair degree of accuracy, to estimate properly the relative value of the methods in question in respect to their immediate mortality and their remote results—the latter as bearing especially upon the all-important question of recurrence or reappearance of the disease.

Partial Removal of the Uterus.—In 1882 Dr. W. H. Baker, of Boston, reported the results of high amputation performed in twelve cases of cancer of the uterus, in which it was hoped the entire disease could be removed.[1] No death occurred from the operation. In one case the disease returned after two months, death occurring in seven months. In another the disease returned almost immediately, and death took place in fifteen months. A third died three months after the operation. In a fourth recurrence took place nine months after operation: date of death not stated. In 1888, at the meeting of the American Gynecological Society, Dr. Baker stated that five of these women were living and well at periods of from six to ten years after the operation.

At the same meeting Dr. Thaddeus A. Reamy[2]

[1] American Journal of Obstetrics, 1882, p. 265.
[2] Transactions, 1888, p. 185.

reported the results which he had obtained by amputation in 55 cases. These were selected from about 300 cases of uterine cancer of all grades, because of the apparent possibility in them of entirely removing the diseased structures. There were two deaths—a mortality of 3 6 per cent.

From Dr. Reamy's report it appears that in 2 of the cases the ultimate result was unknown; in 14 there was recurrence of the disease within one year and subsequent death; in 8 there was recurrence in two years: in 4 there was recurrence at periods varying from two to four years. In 20 there was no recurrence, the periods of immunity being from two to eight years, and 2 of the patients included in the number died from other causes. Of the entire number, 3 others died from other causes, and free from recurrence of cancer, at twelve, thirteen, and fourteen months respectively after operation.

In the *Annals of Gynecology*, January, 1889, Verneuil records his experience with this method of treatment. His cases were 22 in number. There were 2 deaths. In 9 of the cases there was recurrence of cancer in the cervix, while in 12 the cervix remained free from disease, although 1 of the patients was under observation for seven years. Verneuil classifies his cases into two series, the first series embracing the cases operated upon down to the end of 1884, being 17 in number, and the second series including those operated upon since 1884, 5 in number. The average length of life after operation in the first series was twenty-three months, and in the second twenty-nine months.

In 1887 Hofmeier published a table of 96 cases in which partial amputation was done at Berlin. The mortality was 7.4 per cent.; 19 of these patients were living at the end of four years after operation.

Since March, 1882, I have performed partial amputation of the uterus for cancer in 30 cases. Two deaths resulted directly from the operation—a mortality of 6.6 per cent. Of the 28 who recovered 11 are living and were in good health very recently. The periods which have elapsed since the date of the operation in these cases are as follows: In 1 six years and three months; 1 five years and nine months; 3 over four years; 1 over three years; 3 over two and a half years. In addition to the foregoing 2 others are living, but as the operations were made upon them less than two years ago, I have not included them.

Some of the cases are embodied in this report only for their bearing on the question of immediate mortality, the disease having been so far advanced

TABLE SHOWING THE RESULTS IN THIRTY CASES OF HIGH AMPUTATION OF THE UTERUS FOR CANCER.

No	Initials of patient's name.	Residence.	Age.	Date of operation.	Result	REMARKS.
1	R. M.	Englewood, Ill.	41	March 17, 1882	D.	Death on sixth day.
2	K. M.	Chicago	45	April 17, 1883	R.	Died eight months after, from recurrence of disease.
3	S. M.	Chicago	45	June 16, 1883	R.	Recurrence in four months. Date of death not known.
4	N. A. L.	Ottawa, Ill.	32	August 15, 1883	R.	Had a child two years later. Alive and well in October, 1889, six years and two months after operation.
5	M. S.		54	Jan. 29, 1884	R.	Was "perfectly well" June, 1887, three years and seven months after operation. No later history.
6	T. Y.	Chicago	41	Feb. 6, 1884	R.	No symptoms of recurrence Nov. 1, 1889, five years and nine months.
7	G. M.	Chicago	57	April 12, 1884	R.	Recurrence in eleven months; death in fifteen months.
8	L. G.	Chicago	26	April 14, 1884	R.	Recurrence in two months; death in four months.
9	O. S.	Chicago	41	May 25 1884	D.	Death on fifth day.
10	J. M.	Mattoon, Ill.	38	May 5, 1885	R.	Disease recurred in parametria. Death four and a half months after operation.
11	A. M.	Chicago	48	May 30, 1885	R.	No recurrence. Health good August, 1889, four years and three months after operation.
12	H. H.	Chicago	72	June 17, 1885	R.	Subsequent history unknown.
13	M. W.	Dubuque, Ia.	50	Sept. 23, 1885	R.	No return; health good four years and two months after operation.
14	M. J.	Chicago	40	Nov. 25, 1885	R.	Well and free from recurrence four years after.
15	R. M.	Leavenworth, Kansas	50	Dec. 2, 1885	R.	Well February 11, 1886; no later report.
16	L. H.	Chicago	47	May 8, 1886	R.	Recurrence in five months; death in eight months.
17	A. C.	Chicago	51	June 24, 1886	R.	Death in nine months from recurrence.
18	R. L.	Dubuque, Ia.	64	Oct. 23, 1886	R.	No recurrence three years after.
19	E W.	Aurora, Ill.	50	Feb. 14. 1887	R.	No recurrence Nov. 1889, two years and nine months.
20	R. S.	Chicago	40	Feb. 22, 1887	R.	Well and free from return at end of two years and eight months.
21	J. L.	Chicago	38	March 10, 1887	R.	No return. Health good two years and seven months later.
22	E L. T.	Walkerton, Ind.	42	Dec. 21, 1887	R.	Recurrence in four months; date of death unknown.
23	E. K.	Chicago	40	April 30, 1888	R.	Recurrence and death in six months.
24	I. J.	Chicago	64	May 3, 1888	R.	No recurrence in Sept. 1889, one year and three months.
25	A. E. W.	Oskaloosa, Ia.	57	May 22, 1888	R.	Died three months later.
26	M. M.	Fort Wayne, Ind.	54	July 14, 1888	R.	Recurrence and death nine months later.
27	J. H.	Evanston, Ill.	55	May 17, 1889	R.	Disease not all removed; symptoms continue.
28	E. J.	Chicago	42	July 29, 1889	R.	Symptoms of recurrence at four months.
29	E. P.	Chicago	40	Oct. 29, 1889	R.	Too soon to know remote result.
30	L. M. W.	Waverley, Ia.	65	Nov. 8, 1889	R.	Too soon to know remote result.

at the time of operation as to render it certain that the affected tissues could not be safely removed, and in which amputation with accompanying or subsequent curetting or cauterization was used only as the most efficient means of palliation. Such cases were Nos. 1, 3, 8, 16, 22, 25, and 26 of the table. Deducting these 7 and the 2 deaths, 9 in all, from the entire number, it leaves 21 from which to compute the ultimate result of the operation. As already stated, 9 of these are alive and well, from two and a half to more than six years after operation.

From the foregoing table it will be observed that the earliest period in which symptoms of recurrence appeared after operation was four weeks, in a single case, and I am quite sure I did not in that instance remove all of the disease. Indeed, in very many cases—I think I may say all—it is impossible to know in advance of, or during, an operation the extent of cancerous involvement, and hence it is equally impossible to know, except through lapse of time, whether an operation will be or has been radical. And this applies to all operative methods. Whenever symptoms of so-called recurrence are manifested within a few months after an operation, it may very generally be accepted that the fact indicates a continuance rather than a recurrence, and that the disease in such cases has only been partially removed. But while this inability to define the anatomical limits of cancer must always affect the prognosis of an operation, it should not deter from an attempt at removal of the disease in any case in which removal may seem feasible; and it should admonish us to be as thorough in operating as may be consistent with the immediate safety of the patient.

Cauterization.—In *The Lancet* of August 2, 1884, there was published an abstract of a report made by Pawlik of 136 cases of cancer of the cervix which had been treated, at Vienna, by means of the galvano-cautery. The report embraced a period of twenty-three years. Of the entire number, 10 died soon after the operation, making a mortality of 6.6 per cent. Of the 126 survivors, 33 were in good health and free from recurrence at periods varying from two to twenty-one years.

At the annual meeting of the American Gynecological Society, held at Boston in September, 1889, Dr. John Byrne, of Brooklyn, read a paper embodying a report of 367 cases of uterine cancer treated by the galvano-cautery, the observations extending over a period of twenty years. The cases being classified according to the portion of the organ affected, the vaginal portion of the cervix was involved in 59, the entire cervix in 81, both cervix and body in 219, the body alone in 8. The mortality of the operation was *less than 1 per cent.* The period of exemption from recurrence varied greatly according to the anatomical seat of the disease, being greatest in those cases in which it was confined to the vaginal portion of the cervix, and least in those in which the corpus was alone involved. In 36 cases of the former which were kept under observation, the average period of freedom from return was eight years and seven months, 30 remaining well over five years. In the 8 cases in which the corpus was alone diseased, the average period of exemption was two years. In more than one-half of the entire number of cases treated there was freedom from symptomatic return for from three to eighteen years.

Hysterectomy.—The removal of the entire uterus for cancer has been performed probably not less than 1200 to 1500 times. At first the organ was removed by laparotomy, but the operation was attended by such a frightful mortality—not less than seventy-two per cent.—that it is no longer done when the vaginal method is feasible, the latter being vastly safer. Dr. Sarah E. Post has compiled some extremely valuable statistics bearing upon this point. In the *American Journal of Obstetrics* for 1887, she published a table comprising 722 cases, and showed that the mortality of the operation was twenty-four per cent.; and, although the statement that the death-rate is steadily diminishing is probably true as applied to a few operators who have had exceptionally large experience, it is hardly true concerning the great mass of operators. Indeed, I have no doubt that if all the cases were published, it would appear that the mortality of the operation is now, and always has been, considerably over thirty per cent. But, accepting the published statistics as correct, the mortality of hysterectomy, as compared with partial amputation, is four or five times greater, and as compared with cauterization, eight or ten times greater. However, the advocates of hysterectomy claim that, as a compensation for this greater death-rate, the disease is much more likely to be wholly removed, and thus freedom from recurrence, and prolongation of life more certainly secured. The apparent reasonableness of this claim cannot be denied, but, unfortunately, observed facts, now in great number, show conclusively its fallacious character. For example, in 1886, Dr. Post presented a table showing the results of 137 cases; 40 of the patients died—mortality 29 per cent. Of the 97 survivors, only 18 were alive at the end of eighteen months to two years. In Pawlik's 136 cases—one less in number—with a mortality of 10, there were 33 alive and well at from two to twenty-one years. Hofmeier, in the report already referred to, of 96 cases of partial amputation, compared the late results with those in 33 cases in which the entire organ was removed. While 19 of those in whom partial am-

putation had been done were alive at the end of four years, all the others were dead. In Fritsch's 60 cases, with 7 deaths, only 2 were alive after three years. Terrier has recently reported 18 cases. There were 4 immediate deaths: in 3 cases the disease could not be removed, and of the 11 who recovered, only 4 were free from recurrence at the end of two years.

At the last International Medical Congress Martin reported the subsequent histories of 214 women who had survived the operation. Of these, Leopold had 42, Schroeder 46, Fritsch 60, and Martin 66. Of all this number only 5 were alive after four years. Hence, we may say that the successful removal of a cancerous uterus is a very different thing from the successful removal of a uterine cancer.

Having considered the relations which each of the three prominent methods of dealing with cancer of the uterus sustains to the questions of immediate mortality and remote results, it is not difficult to fix their status.

Partial amputation is doubtless a beneficial procedure. With a low rate of mortality, probably not exceeding 5 or 6 per cent., it has in many cases removed the disease permanently, and in others stayed its progress and prolonged life.

In a still greater degree actual cauterization has been shown to be potent for good. The recently published results obtained by Dr. Byrne are wholly without parallel, both in the extremely low death-rate and the greatly prolonged immunity from disease. Dr. Byrne's report is unquestionably by far the most favorable showing that has ever been made concerning any method of treatment for uterine cancer in any considerable number of cases; and as such it distinctly challenges our consideration.

Hysterectomy is a ghastly failure. Not only has it given worse results, both immediate and remote, than other methods of treatment for cancer of the uterus, but I affirm that it is worse than no treatment at all. A hundred women with uterine cancer will live a greater aggregate of years if left alone than if subjected to hysterectomy.

And now, as candid physicians with an honest appreciation of the duties we owe to our patients who place their trust in our integrity as well as in our skill; as men and women willing to be guided by the logic of facts rather than by our predilections or falsely found preferences, what should be our attitude in this matter? If we desire to secure the best interests of a patient suffering with uterine cancer, what method of treatment should we choose for her? Should it be one which with the least risk promises the greatest length of life? or, one which with the greater risk promises the shorter period of immunity from disease and death?

BORIC ACID AND ALCOHOL IN THE TREATMENT OF ACNE.

By SARAH E. POST, M.D.,
of New York.

The suggestion of this plan of treatment was derived from Dr. Lowenberg's report before the International Congress, at Washington, in regard to its efficacy in the treatment of boils. Dr. Lowenberg based his practice upon the following assumptions:

1. Boils are caused by an affection from without—viz., through the ducts of the cutaneous follicles.

2. The successive outbreak of furuncles on the same individual takes place by auto-contagion—that is, through transportation of the cocci upon the skin.

3. Infection from one person to another is possible, and originates from the same process as No. 2.

It then occurred to me that if in a case of extensive local papillary disturbance of nutrition (carbuncle) infection from without had been distinctly proved, it might be logically inferred in the smaller papillary disturbance (boil); further, that if a middle-sized papillary disturbance of nutrition (boil) were due to infection from without, the same might be just as logically inferred for the still smaller local papillary disturbances called pimples or acne.

Arguments in support of this deduction immediately sprang up. Acne often complicates atrophic rhinitis. The discharge in atrophic rhinitis has often the most offensive character, and particles of this discharge may easily be deposited upon the skin. Again, acne often complicates dyspepsia, in which the breath is also loaded with decaying material. If follicular pharyngitis may be produced directly by the irritation of such air, why not also follicular inflammation of the skin? Acne complicates genital irregularities, and it is not impossible that irritating secretions may be carried from these parts to the face.

Another argument is the fact that the sufferer from acne vulgaris has, without exception, an oily skin. He or she is a person to whom everything in the line of dust sticks. There are people whose skin is always clean. They do not bathe more than others, yet they can go through the dirtiest places without being soiled. Such people do not have acne.

Acne is a disease of adolescence. After the beard grows, men do not have acne, and it is quite clear that the beard protects the follicles from the intrusion of foreign particles. Old people, in whom the glands are less active, do not have acne.

However, the truth or falsity of these arguments will in no degree affect the success of the remedy which is here recommended. I commenced using

the boric acid solution for acne in 1887, in the Evening Class for Working Women in the Demilt Dispensary, of New York. The class included, at that time, all varieties of disease.

During 1886 the number thus making application for treatment was 379, of which 6, or 1.6 per cent., were cases of acne. During 1887 the whole number of new cases was 525, of which 10, or 1.9 per cent., were cases of acne. During the latter part of this year the boric acid treatment commenced to be used. During 1888 the whole number of new cases was 552, and of this number 28, or 5.1 per cent., were cases of acne. The increased number of acne cases during this year was clearly due to the success of the medication, for these new cases were, as a rule, introduced by those who had already been successfully treated for the disease. At the beginning of the present year the class had outgrown its accommodations and was divided, so that the comparison could be carried no further.

The directions for treatment were as follows: Bathe the face at night in hot water containing a few drops of ammonia; do not use soap. Rinse the face in cold water. Dry the face. Then apply the solution, sopping it on with the corner of the handkerchief or soft, clean rag. In the morning do not wash the face, but apply the solution. Carry the solution with you, and apply it several times a day if the skin becomes moist.

In very bad cases it was my custom to apply a little ether and remove the comedones with the extractor at the time of the visit. Within a week great improvement would be obtained.

Unlike most applications to the skin, the boric acid solution forms an elegant toilet preparation, as it deposits a delicate powder which is scarcely perceptible, and yet serves to remove the "shine" from the face. I think that men, with their covered faces, scarcely realize the necessity of women for some form of face powder, especially the woman whose face is flushed with household work. It has occurred to me that the alcohol might be the active agent in the cure of acne, but without the powder which it carries the alcohol would not be tolerated, as it leaves a glistening surface on the skin.

The solution which I use consists of half an ounce of boric acid in eight ounces of alcohol, to which perfume may be added, if desired.

INDIVIDUALITY THE BASIS OF RATIONAL CLIMATO-THERAPY.[1]

BY G. E. ABBOT, PH.D., M.D.
BRYN MAWR, PA.

IT is of frequent occurrence that known diseases are subjected to imperfectly understood climatic treatment—important conditions and relations being overlooked in superficial advice, or lost in too much generalization. So with the common error of ascribing to climate, disturbances which are incident either to acclimatization, erroneous treatment, or the patient's carelessness. If it were not for these avoidable mistakes of judgment, a systematic differentiation of climates long since might have been made.

The Climato-therapy of to-day deals largely in speculation and experimentation, but a more careful attention to conditions in their relation to results will tend largely to relieve this department of practice of its present uncertainty. The demonstrated or accepted facts of physiology, meteorology, and climatology can be known, and utilized by a common-sense application to the needs of the patient. The treatment of classified disease by classified climate is as brilliant as routine bedside practice; each case must stand alone, and the practitioner learns that success depends upon the ready appreciation of a something called individuality, and the comprehension of its subtle influence in modifying the disease and remedy as observed in the case under treatment.

Believing that the principle of individuation is applicable to all the factors involved in a given case, we define the basis of rational Climato-therapy to be, *the certain knowledge of the individuality of physician, patient, and climate.* This knowledge is intuitive and discursive; and the notion of such individuality implies an innate power of discrimination, as well as careful comparative study. Otherwise expressed—the physician, appreciating the personal equation, must realize the importance, and conceive of the reality of the patient and the climate which marks all the others with a difference and constitutes the one under consideration.

The following, purely suggestive in character, may serve to convey approximately an idea of the difficulties attendant upon drawing inferences as to treatment.

Certain rudiments of meteorology and meteorological observations are involved in Climato-therapy. In daily thermometric readings we note that, on mountains the daily maximum comes earlier than on plains or in valleys.—The greatest differences in amplitude are in the strata next the ground.—The air above a convex surface is warmer in winter and at night, it is also cooler in summer and during the day; and the yearly as well as the daily amplitude is less than upon a concave surface.—The daily amplitude on high elevations and in high valleys is often greater than in low-lying plains, depressions, or deep valleys.—Height in itself does not decrease the amplitude.

With small daily changes in absolute, the relative humidity decreases during increasing temperature, and increases during decreasing temperature: *i. e.*,

[1] Read before the American Climatological Association, June, 1889.

where the daily amplitude is great. The daily change in relative, is more important than that in absolute humidity. In mountain regions, the daily period of the absolute, as well as of the relative humidity is complex; and differs from that of the plains in having a smaller daily amplitude, depending upon the small temperature amplitude and upon moist currents. In elevated valleys, the daily relative humidity amplitude may be greater than in lower valleys, as is the case with the temperature amplitude.

In climatology and climato-therapy it should be remembered that a climate geographically severe, is rendered relatively mild by topographical and local conditions: that the climate of convex surfaces is influenced more by relative elevation and form of surface, than by absolute height: that the rapidity of vapor formation on mountains is increased by lower pressure, and lessened by the general greater relative humidity, as on plains when the relative amount of vapor is smaller and the barometric pressure is greater; and that low barometer, with high relative humidity, often equals high barometer with low relative humidity in its climatic effects.

Single climatic factors have slight purport; averages mean little unless correctly associated. The first practical question to arise is, The temperature of which air shall be measured? One is of climatological, the other of medical import. Then we should know, not so much the absolute as the relative temperature;—not so much the yearly mean, as the mean winter temperature, and the maximum and minimum of the day and of the month; and also the number of hours of the lowest as well as of the highest temperature in every day in each month.

In regard to rain we require, not the mean or total fall, but the mean monthly fall expressed in percentage of the yearly amount; the quantity of rain and the average number of hours of rain per rainy day. With cloudiness it is necessary to know the mean duration of sunshine, expressed in hours per mean day of the month, and its relation to the possible sunshine. The humidity of a locality is unknown, unless the mean in one of the coldest as well as warmest hours of the day is given; and important as is the actual saturation deficiency, still more so is the sensible deficiency in saturation, *i. e.*, the difference between the actual relative humidity of the air at a given temperature, and that necessary to saturate it, were the temperature 98.5° F., is the sensible relative humidity.

The actual velocity of the wind is not so important as its relative, *i. e.*, its sensible velocity; the saturation deficiency and the velocity of the wind determining the evaporation. The effect of these factors on a given absolute temperature is equal, according to Smart, to a calculated degree of calm, dry cold, *i. e.*, the sensible temperature.

The benefit accruing from climatic warmth has its limitations. It may retard the progress of diseases of the lungs, but more probably the improvement depends upon conditions in the case of the patient. An equable temperature, with considerable moisture, exerts untoward local and general influences; while changes in humidity or velocity of winds are more trying than variability in temperature. In general, warm, humid climates are sedatives, dry climates stimulants; yet either continued taxes the nervous system. Since "life points to a change in phases of rest and excitement," variations, within certain limits, probably favor the important functions of life more than relative uniformity.

Improvement due to mountain climate comes not from, but in spite of, the rarefied air, and depends upon its aseptic qualities, strong winds, and an atmosphere in which exercise can be taken at all seasons. Improvement due to ocean climate comes from the antiseptic qualities of the air, the smaller difference between day and night, sun and shade, greater protection from chilling influences, and less demand for muscular activity to compensate heat-loss. In the former, the rarefied air expands the lungs, thereby compensating the pressures and facilitating the blood-flow; in the latter, the high pressure accumulates in the lungs the greatly increased amount of oxygen in the air, while the small quantity of carbonic acid present promotes the carbonic acid exhalation. Sea climate increases appetite, bodily weight, excretion of urea and feces, and decreases uric and phosphoric acid excretions; while in mountain climates there is less demand made upon the organs of assimilation, the appetite despite exercise is moderate, the excretion of urine and feces rather decreased, and there is little or no bodily increase. Both climates give equally good results in the same disease; and each, in patients with marked differences in degree of vitality—why? Individuality.

The more closely Climato-therapy is studied, the more evident it becomes that successful treatment depends less upon the absolute, than upon the relative conditions of climate; less upon the critically differentiated disease than upon the patient—his physiological resistance, recuperative power, and environment; less upon the physical factors than upon the individualities of both patient and climate. An opinion in Climato-therapy presupposes an intimate acquaintance with all the factors entering into any one case—of these, Individuality is essentially preëminent.

CLINICAL MEMORANDA.

ANATOMICAL.

The Remedy for the Annual Scarcity of Dissecting Material.—At this time of the year there is a periodical scarcity of human bodies for the study of practical anatomy and operative surgery in our medical colleges. It seems strange to me that the annual deficit has never been

met by the simple and perfectly satisfactory device of using the bodies of dogs and cats for such purposes.

It is well known to all of us who have been taught anatomy and surgery, that very nearly fifty per cent. of the dissecting material supplied to students is ruthlessly wasted. Subjects are constantly allowed to dry up or decay by careless and indolent students, while other members of the class are anxiously waiting to have parts assigned to them. The beginner in dissecting very often wastes material from ignorant use of the scalpel; the older student does the same because of his haste to study only nerves, vessels, and viscera.

The principal values of dissection are to teach the first-year student the use of the scalpel and forceps; the appearance of muscle, fascia, artery, and nerve, and the location of the larger viscera. This could be done as well on the body of a dog or cat as on a human cadaver; and at probably one-tenth the expense. Again, the classes in operative surgery are taught, as a first step, to make cutaneous incisions and to insert sutures. Certainly these proceedings are readily learned on the shaved trunk of one of the lower animals. In fact, many of the more important operations could be taught as well, or almost as well, as these. Trephining, resection of bone, excision of testicle, suture of intestine, intestinal anastomosis, excision of the eye, tenotomy, etc., are perfectly demonstrable on the lower animals.

After a course of this kind in certain classes, the students could be put to work on human structures, when it would be found that their trained hands and thoughtful brains would make good use of the opportunity given to study higher anatomy and operative surgery.

This method would be valuable also in giving them some insight into comparative anatomy, of which many of us know so little. It would be a sort of unconscious biological training of no mean import.

It is understood, of course, that I do not mean to practise vivisection in this uncontrolled manner; but to do this work upon dead animals obtained from the dog-pound of the city; if necessary, inferior grades of animals could even be bred for the purpose, as we breed food animals for the slaughter-house. It must, however, be done humanely and scientifically, not brutally.

Students in many schools learn most of their anatomy from books, because of the impossibility of getting human bodies in quantity, and yet an unused wealth of canine anatomical material is always at hand.

JOHN B. ROBERTS, M.D.

HOSPITAL NOTES.

OPERATION FOR DOUBLE OVARIAN TUMOR. ARTHROTOMY OF ELBOW-JOINT. EXCISION OF HIP-JOINT. EXTERNAL URETHROTOMY.

BY CHARLES B. NANCREDE, M.D.,
PROFESSOR OF SURGERY AT THE UNIVERSITY OF MICHIGAN, ANN ARBOR.

OPERATION FOR DOUBLE OVARIAN TUMOR, FOLLOWED BY RECURRENT HEMORRHAGE; RECOVERY.

PROFESSOR NANCREDE called attention to the danger of operating in a general hospital, unless the strictest aseptic precautions were taken. He laid special stress upon the difference between *aseptic* and *antiseptic* surgery, contending that the former was the highest expression of Listerism; that Tait and his school really owed most of their success to the fact that Lister had shown that "something," which adhered chiefly to the patient's person, the surgeon's hands, and his instruments when introduced into the abdominal cavity, caused septic peritonitis, etc. He insisted upon the impropriety of using antiseptics in the abdominal cavity, and told the class that the patient had been prepared for operation by a thorough bath, special attention being paid to cleansing the umbilical depression. The operator also had carefully washed himself. His instruments (solid ones) had all been boiled, as had his ligatures, and the sponges were rendered aseptic. The toilet of the peritoneum would be made with boiled, recently distilled water. No antiseptic would be used, except to wash off the abdominal wall before making the incision, and a pad of antiseptic gauze, wrung dry, placed along the line of incision, as a permanent dressing. The field surrounding that of operation would be protected by towels wrung out of corrosive sublimate solution.

The lecturer then described the course and history of his case, which showed that constant vomiting had existed for nearly seven months, reducing the patient to a state highly unfavorable for operation. The tumor was firmly impacted in the pelvis, causing nearly complete obstruction of the rectum, rendering death only a question of time.

A very long incision was found necessary, and the delivery of the nearly solid tumors was most difficult. Owing to continued oozing, the source of which could not be detected—re-ligation of one pedicle being resorted to—drainage would be instituted, since his rule was, as was Greig Smith's, "When in doubt, drain."[1]

ARTHROTOMY FOR UNREDUCED BACKWARD DISLOCATION OF BOTH BONES OF THE FOREARM.

In this patient a fall, between four and five months ago, had resulted in a dislocation which had not been reduced, it being thought that a fracture of the humerus also existed. Although Professor Nancrede had once reduced a similar displacement at the end of ten weeks, he could not do so in the present case, elbow luxations becoming "ancient" sooner than those of any other joint; indeed, at the end of a month it is often impossible to replace the bones without operation.

Three courses were open in such cases—in the young, arthrotomy; in middle age, excision; in the really old, intentional fracture of the olecranon process under an anæsthetic, and obtaining ankylosis in a good position—a right angle, if a movable joint could not be secured.

Making an incision as if for excision, freeing the ulnar nerve, dividing numerous adhesions, the olecranon was then sawn across, and, after removing a small osseous fragment adherent to and blocking up the trochlear

[1] This proved to be the means of saving the patient's life, for, upon reacting some hours later, severe arterial bleeding occurred; the abdomen was reopened, and, although no distinct bleeding points were detected, the pedicles were re-ligated, it being thought that some vessel had been damaged by the aneurism-needle when perforating the pedicle, or that it contained myomatous tissue, causing it to shrink. The woman recovered, apparently as well as if no second operation had been required.

surface of the humerus, the bones were with great difficulty reduced. Free drainage was instituted, the olecranon wired to the shaft, and the arm put up on an obtuse-angled splint, the Professor stating that the arm would be gradually brought to a right angle or less, as soon as the contractured state of the triceps could be overcome.

EXCISION OF THE HIP-JOINT.

The lecturer called attention to the evils of prolonged bone suppuration, such as amyloid degeneration of the liver, kidneys, and bloodvessels of the intestines, stating that in his experience, for the diarrhœa resulting from the last-named complication, nitrate of silver in appropriate doses had proved most efficacious, although, of course, not curative.

It might be asked, How did he know that the bones composing the coxo-femoral joint *were* involved? The reasons were that the child had latterly waked up frequently in the night with severe pain in the limb, and found himself forcibly grasping and steadying the thigh with both hands—*i. e.*, he had the distinctive "starting pains" of inflammation of the sub-cartilaginous lamellæ of bone, meaning also more or less erosion of the articular cartilages. Doubtless, in addition, under ether, by proper manipulation, the eroded bony surfaces could be brought into apposition, the granulations torn away, and "grating" elicited.

Under full antiseptic precautions, the joint was excised by Heyfelder's incision, which was usually employed by Professor Nancrede, the femur being sawn so as to remove nearly all the trochanter major, to insure free drainage. The upper part of the acetabulum being carious, it was removed with the burr, the wound drained, and put up in *abduction*, both to lessen deformity and the shortening of the limb.

TRAUMATIC STRICTURE; PERINEAL FISTULA; EXTERNAL URETHROTOMY.

The next patient, aged fifteen years, about three years since, while coasting, fell from the sled and struck his perineum on a board imbedded in the ice, containing some projecting nails, which latter divided the urethra, as shown by the urine passing freely from the wound during the next act of micturition. For a few weeks a little urine was passed by the urethra, but after this time none.

After etherization, first a fine probe, then a director, was passed along the fistula, and a sound down to the occluded portion of the urethra, which was at about the position formerly occupied by the bulb. A median incision exposed the point of the sound, which was made to emerge at the perineal wound, and the strictured tissue was freely dilated and divided by the knife. Next, the posterior portion of the urethra was found, freely opened by dissecting down upon the track of the fistula as indicated by the director, and a soft-rubber catheter, stiffened by a stylet, introduced into the bladder, the instrument being guided along the urethra by a broad-grooved hernia director, which, Professor Nancrede stated, was the best instrument for this purpose. He detailed the symptoms of a ruptured urethra, and called attention to the frequency of the accident from falls upon the perineum and from crushes of the pelvis, and warned the class that after such injuries the condition of the bladder must be at once investigated. He further stated that when decided urethral laceration was demonstrated by the passage of blood with a little urine on the first attempt at micturition, followed by total inability to empty the bladder, and the attempt to catheterize failed, owing to the manifest laceration of the urethra, a median perineal incision should be made, the two extremities of the urethra sought, a catheter introduced, and the wound allowed to heal by granulation. Even with an external wound, as in this case, the urethral ends should have been sought and kept in apposition, when the present operation would have been unnecessary. With no external wound, extensive urinary infiltration with gangrene of the cellular tissue, sapræmia, and death commonly results, unless a free perineal incision is promptly made.

MEDICAL PROGRESS.

Amylene Hydrate in Epilepsy.—DR. WILDERMUTH, of Stuttgart, has had very satisfactory results in the treatment of epilepsy with amylene hydrate, particularly in cases with nocturnal paroxysms. His studies included thirty men and thirty-six women suffering from the disease. The amount given was from one to two drachms daily in two or three doses, administered in wine or cider, or in severe cases in smaller doses administered hypodermically. In some cases a continuous sleepiness was observed, which, however, often disappeared after the patient had become accustomed to the drug without lessening the dose. In many cases the anti-epileptic effects continued for six or eight weeks after the drug was discontinued. The author considers amylene hydrate indicated:

1. In cases with frequent convulsions.
2. In severe bromism to control the paroxysms.
3. In nocturnal epilepsy, where it may be alternated with bromides, in recent cases combined with atropine.—*Therapeutische Monatshefte*, December, 1889.

Dr. Dobell's Treatment of Influenza.—In the *British Medical Journal*, December 21, 1889, DR. DOBELL advises that at the beginning of an attack of influenza the patient should go to bed at once and take hot gruel, hot tea, and beef-tea for diet during the more acute state, resuming ordinary solid meals as soon as practicable. The bowels should be kept well open (but not severely purged) by any aperient known to act most kindly with the patient. The use of the following inhalation should be begun immediately:

R.—Creasote Oil of cloves	.	of each 1 drachm.
Oil of eucalyptus	. . .	1 ounce.
Camphorated tinct. of opium		2 ounces.—M.

Shake well, and add one teaspoonful to three pints of boiling water; wait two minutes to let the hottest steam pass off, and then hold the face well over the vessel, and throw a light handkerchief over the head; shut the eyes, and let the forehead and face be thoroughly exposed to the steam, which should be drawn through the nostrils and blown from the mouth. Continue this as long as steam lasts (about fifteen minutes), and repeat every two hours.

In the interim, gargle occasionally with hot water, and let all the secretions from the nose and throat be ejected. Internally, the following should be administered:

R.—Spirit of camphor		1 drachm.
Spirit of nitrous ether	} of each	1 ounce.
Comp. tinct. of cinch.		

One teaspoonful in water every three hours. If the temperature rises above 101° F., take five grains of antifebrin in two tablespoonfuls of beef-tea, and repeat every hour till the temperature falls to 100°, continuing the inhalations and mixture as before. If pain or oppression of the chest sets in, apply hot poultices. No danger need be apprehended if the above directions are followed in good time. The doses ordered are for persons over twelve years of age, and must, of course, be reduced for those who are younger.

Sozoiodol in the Treatment of Burns.—DR. OSTERMAYER, in the *Deutsche medizinische Wochenschrift*, advocates sozoiodol for the treatment of burns. Like iodoform, it has the property of allaying pain, but in addition it prevents suppuration. It is odorless and perfectly safe. When a burn has been sustained the blisters are opened and the contents removed with sterilized or antiseptic cotton. Immediately a 10 per cent. mixture of sozoiodol in powdered starch or Venetian talc is dusted on profusely, and the whole is then protected by a layer of cotton which is held in place by a roller bandage. After twenty-four hours the beneficial effect of sozoiodol becomes evident. Repair is completed without suppuration in a remarkably short time and painlessly. Of course no danger from poisoning exists, even if the application is over an extensive surface. This is true not only of burns inflicted by direct flame or hot steam, but likewise those due to chemical action. It has been observed that persons suffering from caustic potash burns in the face have made a rapid, painless, and excellent recovery. Scars fail to appear when the wound is treated with sozoiodol.—*Pittsburg Medical Review*, December, 1889.

The Significance of Erythema.—Erythema multiforme is more and more growing in importance as a symptom or precursor of not a few grave diseases. It does not do for us now to regard an attack of it as simply due to indigestion. It has been shown that the occurrence of erythema may mark the beginning of typhoid fever, may occur as one of the symptoms of acute or chronic malarial disease, may be a manifestation of a rheumatic or lithæmic state, or may even, as it were, be an abortive manifestation of any of these diseases. Our attention is again drawn to the fact by Dr. Moncorvo, of Rio de Janeiro, who has recently reported two cases of erythema nodosum occurring in the course of acute malarial disease and yielding promptly to quinine.—*New York Medical Journal*, January 4, 1890.

The Uses of Cocillana.—At a recent meeting of the New York Academy of Medicine, DR. R. W. WILCOX stated that he believed cocillana to be superior to apomorphine as an expectorant, except within the first forty-eight hours of acute bronchitis. It was certainly preferable to ipecacuanha in that it did not so readily cause nausea and metallic taste in the mouth, and, moreover, assisted regular movement of the bowels. It was immeasurably safer in any stage of acute bronchitis than pilocarpine, because it did not depress the heart's action; though it must yield to carbonate of ammonium in chronic senile bronchitis. On the whole, he thought it could fully replace ipecacuanha in every sphere of action, and that in many cases it could be substituted with advantage for apomorphine, carbonate of ammonium, strychnine, and other drugs classed with more or less reason as expectorants.—*Boston Medical and Surgical Journal*, January 2, 1890.

Disinfectant Injection.—The *Gazette de Gynécologie* gives the following formula for a disinfectant injection:

Salicylic acid	} of each	30 grains.
Thymic acid		
Essence of amber		20 drops.
Essence of verbena		30 "
Alcohol (90°)		4 drachms.
Cologne water		1 ounce.
Distilled water		10 ounces.

A tablespoonful of this solution is to be added to two quarts of water, and used as a utero-vaginal douche two or three times in twenty-four hours whenever the lochia are fetid.

Central Motor Innervation of the Larynx.—In the *British Medical Journal* of December 21, 1889, DR. FELIX SEMON and MR. VICTOR HORSLEY publish the following preliminary note:

In 1886 and 1887 we carried out a large series of experiments (over 100) on different species of animals—monkeys, dogs, cats, and rabbits—with the view of investigating the central motor innervation of the larynx. Circumstances have hitherto prevented us from completing these researches; but we have received so many requests from those interested in the subject that we should publish our results, if only in a preliminary form, that we desire to comply and to add the deductions which we think may be legitimately concluded from our experiments. At the same time we wish to state distinctly that this is only a preliminary communication, and that we shall lay a full account of the experiments on which our conclusions are based, together with a complete theory of the motor innervation of the larynx, before the Royal Society in next May or June. We shall also give a full description of the same before the International Medical Congress at Berlin in August next.

The conclusions which we have arrived at are as follows:

1. There is in each cerebral hemisphere an area of bilateral representation of the adductor movements of the vocal cords, situated in the monkey[1] just posterior to the lower end of the præcentral sulcus at the base of the third frontal convolution, and in the carnivora in the præcrucial and neighboring gyrus. This area has a focus of intensest representation in the anterior half of the foot of the ascending frontal convolution. Stimulation of this point produces complete bilateral adduction of the vocal cords, which lasts as long as the stimulation is continued. Should, however, the latter be unduly prolonged, the "bésoin de respirer" overcomes the influ-

[1] Demonstrated to the Physiological Society, 1887.

ence of the artificial stimulus and evokes a momentary but powerful abductor movement of the vocal cords. Stimulation of the more peripheral parts of the area evokes less and less perfect adductions as we proceed from the focus outward, and when the extreme margin of the area is excited, only what is known as the "cadaveric position" is assumed by the vocal cords.

The above description applies to the monkey, dog, and rabbit. In the cat we have observed curiously different conditions, for which, at present, we are not prepared to offer any explanation.

2. We have not been able to find an area of representation in the cortex of the abductor movements of the vocal cord.[1]

3. If one of the cortical areas for adduction be so completely excised that stimulation of the neighborhood of the lesion produces no effect upon the larynx, and if the wound be allowed to heal aseptically, no paralysis of the cords is observed. Further, if subsequently the corresponding area in the opposite hemisphere be excited, just as completely bilateral an adduction of the cords is produced as if the opposite area were intact.

From the above facts we infer that

(*a*) Unilateral irritation produces bilateral effect. Thus clinically in any irritative unilateral affection of this area spasm of the glottis—that is, bilateral adduction of the vocal cords—may occur; for example, in laryngismus stridulus. That this view is not purely theoretical is shown by the association in severe cases of the last-named illness, of the glottis spasm with the so-called carpo-pedal contractions. This association is most easily explained on the assumption that we have an overflow of energy from the laryngeal to the neighboring cortical areas for the limbs.

(*b*) Unilateral destruction produces no effect. There is, therefore, no such thing as unilateral paralysis of a vocal cord from lesion of a cerebral hemisphere, as has been asserted. The truth of our statement is made evident by the fact that motor aphasia is not identical with aphonia. Moreover, the observation by one of us (F. S.) of several patients with complete aphasia and right hemiplegia, only a few hours after the apoplectic stroke, has conclusively shown that in such instances the movements of the vocal cords are perfectly preserved.

4. We have observed that on powerful or long-continued excitation of the laryngeal area true epilepsy of the vocal cords supervenes, gradually spreading to the neighboring muscles of the face, neck, head, and upper limbs. From this we conclude that the epileptic cry is not, as has been so long believed, the result of a discharge primarily from the medulla oblongata, but rather represents a stage in the cortical excitement popularly termed an epileptic fit.

5. Whilst we have found so distinctly specialized an area of representation of adduction in the cortex, and no corresponding area of abduction in this region, we have, on the other hand, found that direct excitation of the accessory nucleus in the medulla oblongata evokes abduction of the cords, and never anything else.

From all the foregoing it follows that our results are in complete harmony with the most recent views of the relation of the cortical to the lower centres; for our experiments have shown that the representation of the laryngeal movements in the cortex is essentially that known as purposive or volitional, since it is adduction—that is, phonation; whilst, on the other hand, the bulbar representation of the larynx is as essentially adapted to the so-called automatic processes of organic life—that is, abduction-inspiration.

Finally, this series of experiments, as well as those we have previously published[1] on the peripheral innervation of the larynx, corroborate in the fullest manner the ideas which one of us (F. S.) put forward in his first papers[2] on abductor paralysis, namely, the proclivity of the abductors to fail in organic, and of the adductors in functional, disease.

Rubidium Bromide in the Treatment of Epilepsy.—According to the *Gyógyászat*, DR. ROTTENBILLER has recently studied the effects of rubidium ammonium bromide upon five epileptic patients, and concludes that in doses of one and a half drachms daily it has a decided influence in reducing the frequency of the attack, and in larger doses is about equivalent to potassium bromide, but, like the latter, it has no permanent effect, the paroxysms returning when the medicament is omitted. The costliness of the drug will probably prevent its coming into general use.—*Internat. klin. Rund.*, Dec. 1, 1889.

Treatment of Locomotor Ataxia.—PROFESSOR LEYDEN, of Berlin (*Internationale klinische Rundschau*, December 1, 1889), writes disparagingly of the utility of drugs in the treatment of locomotor ataxia. Nitrate of silver, chloride of gold, ergot, secale cornutum, belladonna, or arsenic may be employed, but in his opinion they are of little use other than the encouragement they afford to the patient. Iodide of potassium is valuable, not as a curative agent, but to mitigate the lancinating pains. Strychnine, he considers unadvisable from the general muscular excitability which it causes. Mercury can be considered as having a specific influence only in cases of syphilitic origin, though in non-syphilitic cases it may be beneficial to a slight degree. Warm baths, he believes, are the most important means which we possess for the treatment of this disease; but, though of decided benefit, they must not be considered as specifically curative. In giving the baths the patient's comfort should govern the temperature, and great care be taken that he does not become chilled. The duration of each bath should be between five and twenty minutes. In most cases this method of treatment should be used only in the summer months. The effects to be expected from the treatment are: increase of the patient's strength, reduction in the number and severity of the lancinating pains, and excitation of the sensory nerves. Leyden also considers it possible that the baths, to a slight extent, check the progress of the sclerotic process.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 18, 1890.

THE CO-EDUCATION QUESTION AGAIN.

IN another column we print letters received from two female physicians which are sent as replies to the symposium on this subject published some weeks ago, and though in common justice we cheerfully accord these communications proper space, we cannot let the opportunity pass of denying that "the women who, apart from actual uterine disease, are seriously disturbed at menstruation, are women with a distinct neurotic taint. Menstrual disturbance may properly be classed among the hysterical stigmata, and like the others, implies deficient cerebral control and lower nerve centres."

Every physician, almost every layman, can by a glance tell whether a woman's uterine system is actively engaged in menstruating by the change in the expression and the color of the face and bodily activity, and the vast majority of physicians will testify that most young girls of college age are "laid up" for a day or two with menstrual pain or lassitude every month. Elsewhere the writer of one of these letters has shown that 46 per cent. of all women suffer at menstruation; or, to use her own words, 46 per cent. are cursed with "a hysterical stigmata" and have "deficient cerebral control" and "lower nerve centres," or a "neurotic taint." That is, nearly one-half of the women who would go to college are proved by their staunchest defender to be mentally weak! So far as we can see, this is a most useful endorsement of the opinions expressed in the symposium we have published.

It is claimed that the exercise of mind is utterly different from the exercise of muscle, so far as the expenditure of force is concerned, and that, while muscular activity may not be good for the menstruating female, mental activity does no harm. Physiologically this is absurd, for both forms of activity bring on increased blood-supply to either muscle or brain, and both expend units of force. That force is expended in thought is evidenced by logical deduction, by the necessity of using good food, and by the constituents of the urine showing tissue break-down.

Again, the mere fact that one writer knows of women who bathe constantly during menstruation without harm, has naught to do with the question in hand. Most women have learned for themselves that such a practice is evil in its results. The writer of this editorial knows of a woman of eighty-seven years who daily takes a cold plunge bath and enjoys it, but the majority of women at that age would probably not take more than one.

The question of higher education aside, that of co-education asserts itself, and we confess that on a purely philosophical basis our ideas may be considered too æsthetical. If the race is willing to follow out hard common sense in every detail, then let us have the freedom in the relief of bladder and rectum that the lower classes of Europe are forced to allow, and let us have pregnancy, coition, and similar things talked of in the drawing-room. The young girl who can sit in a class-room with young men and be told of the sphincter vagina muscle and its functions in physiological lectures without flinching should certainly not object to much less broad discussiou at a dinner party.

The status of the world should in justice be this, that if women want to do these things, let no one hinder them, but let them know that they are in danger of losing the chief thing that they need, a man's respect, when all their modesty is buried in science. But a few months ago in the confinement ward of a large hospital in this city, sat through the long hours of the night, a younger son of Æsculapius and a still younger daughter who were engaged to be married, and watched the bulging perineum and protruding head or felt the dilated os with student's finger-tip. Romantic scene, no doubt, of youth and science, wed and bred of true philosophy,

but, nevertheless, somewhat startling to those whose education was received in days when sentiment prevailed.

THE TREATMENT OF STRICTURE OF THE URETHRA BY MEANS OF ELECTROLYSIS.

While waiting to pass judgment upon this question, which for some time past has occupied a prominent place in current medical literature, the profession will closely scrutinize all communications on the subject, either *pro* or *con*, which come before it.

In the *Gazette Médicale* of November 9th, Dr. Boisseau du Rocher contributes a description of a new form of electrode, overcoming certain objections in those of the usual shapes, and enabling him to obtain excellent results, which he promises to give us in full at some future date. Linear electrolysis, he says, yields results that are far from satisfactory, while the process conducted with an olivary electrode and with feeble currents has furnished only insufficient results. The new electrode has a peculiar olive shape, being two cones united by their bases, one of them, that connected with the shaft of the instrument, being much longer than the other. The surface of the double cones is deeply grooved or fluted lengthwise. The reason given for this arrangement is, that owing to the unequal conducting power of the tissues, a greater or less extent of the surface of the ordinary olive-shaped electrode is inactive, the current choosing, of course, the points of least resistance. By the grooving of the surface the points of contact are limited, and an equal action on all parts of the stricture insured. The peculiar shape of the electrode makes it possible to confine the electrical action to the region of stricture, and to spare the healthy part of the urethra.

While these refinements appear to be based upon a clear comprehension of what must be accomplished by the electrolytic treatment of stricture, as an operative procedure, they do not remove from the method that which appears to us the strongest objection to it, namely, that it deals with strictures of all forms and all varieties in practically the same manner. We are among those who are unable to see, as yet, any virtue in the process other than the dilatation accomplished mechanically by the electrode used. We stand, however, ready to be convinced. No one plan of treatment will ever be successful in curing stricture of the urethra. With the location of the contraction, the degree of density, its extent, and the presence or absence of a tendency to recontraction, the surgeon must vary the means employed, and accordingly will make his choice from the methods of dilatation, internal dilating urethrotomy, and external urethrotomy, each, as a rule, meeting, so far as we can see, every requirement of the class to which it is adapted. If electrolysis can accomplish anything more we shall gladly tender to it the first position, if it can prove its claims.

REVIEWS.

Artificial Anæsthesia. By Lawrence Turnbull, M.D. Third edition, revised and enlarged. 12mo. Philadelphia: P. Blakiston, Son and Company, 1890.

The fact that the third edition of this book has appeared very soon after the second was put on the market shows that the labors of the author have been duly appreciated. Dr. Turnbull has taken a great deal of trouble in all the editions of his book to obtain the latest facts in regard to this most important subject. The third edition has been particularly well cared for in this respect, to such an extent indeed that the book is considerably increased in size as well as value. To the physician wishing to post himself as to anæsthetic drugs of all kinds, whether their use is local or systemic, we heartily recommend Dr. Turnbull's work as one embodying everything of importance in regard to the subject of which it treats, as well as an amount of historical and practical information with which every one should be acquainted. Not the least useful portion is the consideration of the relative values and dangers of the various anæsthetics, and the methods of treatment to be employed in cases of untoward symptoms asserting themselves.

CORRESPONDENCE.

NEW YORK.

To the Editor of The Medical News,

Sir: At the last general meeting of the Academy of Medicine, Dr. Joseph D. Bryant, Surgeon-General of the State and Commissioner of the City Board of Health, read a paper on "The Health Department and the Conference Committee of the Academy of Medicine." This committee was appointed some time ago, when Dr. Jacobi was President of the Academy, and the results of this coöperation with the Health Department, as shown by Dr. Bryant's report, have been very satisfactory, particularly as regards the matter of contagious diseases. The President of the Board of Health and a considerable number of prominent physicians were present and took part in the discussion.

The Mayor and a party of other officials recently made a visit of inspection to the auxiliary insane asylum of the Department of Charities and Correction, situated near Central Islip, Long Island, which was provided for

by act of the Legislature in 1885, as a means of relief for the overcrowded institutions on Ward's Island. The property purchased consists of about 960 acres of almost level, sandy soil, with here and there a thin top layer of vegetable mould; building operations were begun eighteen months ago. In April last the first detachment of inmates was sent down from Ward's Island, and already the results of the experiments of this country colony have been extremely gratifying. There is now a collection of frame buildings, most of which are but one story in height, having steep shingle roofs and sheltered porches, with enclosed galleries connecting the different groups. There are three groups of ward buildings, or pavilions, each consisting of three dormitories and a dining-hall, and an administration building of two stories, in which the physician in charge resides with his family. There are also a bakery and cookhouse, storehouse, tailor's shop, laundry, water-tower, stable, icehouses and boiler-house, and blacksmith and carpenter shops are in course of construction. In all there are twenty-one buildings of various sizes, and the total cost of these, with the land, has been about $244,000. There are at the present time 309 male patients in the institution, which is about sixty short of its comfortable capacity, and for the care of these there is a force of thirty-three physicians and attendants. A considerable tract of land is under cultivation by the inmates, and nearly all the cooking, tailoring, mending, washing, cleaning, and other labor about the institution is also done by them. The present system is capable of almost indefinite expansion, the site being sufficient to accommodate comfortably 6,000 patients, and efforts will be made by the department to secure an appropriation of $250,000 for more buildings and improvements at the coming session of the Legislature.

A recent event of interest has been the organization in this city of the "Association of Life Insurance Medical Directors of America," the object of which is announced to be "the promotion of medical science as applied to life insurance by the personal intercourse of the members, presentation of papers, discussions, and such other methods as may be found desirable, and also the encouragement of social and personal relations between its members, and the advancement of the general interests of life insurance." The officers elected were the following: President, Dr. J. M. Keating, of the Pennsylvania Mutual Company; vice-presidents, Drs. G. W. Russell, of the Ætna, and Louis McKnight, of the Northwestern Mutual; secretary, Dr. Frank Wells, of the John Hancock; treasurer, Dr. J. W. Brannan, of the Washington; executive committee, Drs. J. M. Keating, Frank Wells, J. W. Brannan, Henry Tuck, G. S. Winston, E. W. Lambert, and Edgar Holden. The next meeting will be held in May, 1890, and after that, May is to be the regular month for the annual meetings.

At the annual meeting of the Council of the University of the City of New York, it was announced that there are this season 650 students in the Medical Department, and that the original work in physiology, biology, and pathology in the Loomis Laboratory up to the present time, including the report of experiments made with the Brown-Séquard elixir, will soon be published in the form of Loomis Laboratory Proceedings.

Early in December the new Babies' Hospital, which, it is claimed, is the only institution in the city exclusively devoted to the care of infants, was inaugurated with appropriate ceremonies. A portion of its work will be the training of girls for children's nurses, and in connection with it there is also to be a post-graduate course for instructing trained nurses in the special nursing of sick children.

Another melancholy illustration of the extreme caution that is necessary in handling sulphuric ether in rooms where there is artificial light is furnished by the recent death by burning of a female nurse in the private hospital of the homœopathic surgeon, Dr. William Todd Helmuth. She was pouring ether from one bottle into another, when the vapor became ignited from the gas or a lamp and one of the bottles exploded, with the result of setting fire to her clothing and burning her so severely before assistance arrived that she died the next day. The victim was a trained nurse, twenty-six years of age, and had been in the hospital for six years.

One of the daily papers publishes the following interesting item: The residents of Williamsburg are discussing a harrowing report concerning the material of which bologna sausage is manufactured in Newtown. Henry Meyer, of that place, has been found by Health Officer Wickam using horse meat in the manufacture of his sausages. The Newtown Board of Health met, and decided that there was no law to cover the case. But the people of Williamsburg are dissatisfied with such a decision, and the Newtown sausage is no more prized as a family succulent. Over the bridge, the news has travelled quickly. At this very time, when the fascinating Frankfurter is showing up on every Bowery corner, the dread of equine sinew is threatening trade. For those New Yorkers who are distrustful of bolognas and Frankfurters, however, Dr. Edson and Chemist Martin, of the Health Board, have a reassuring word. "There are no horse-meat sausages made in New York," they say. It is a matter of conjecture whether they are imported.

THE HIGHER EDUCATION OF WOMEN.

To the Editor of THE MEDICAL NEWS,

SIR: I have noticed that one of the distinguished contributors to your interesting symposium on "The Higher Education for Women" has quoted my statistics in regard to menstrual disabilities, but it is rather singular that neither he nor anyone else observed that these statistics were chiefly obtained from women who had received only a limited education. They are not, therefore, really applicable to the question at issue further than to show, conclusively, that privation of intellectual training is entirely inadequate to secure to women the blessings of health. This, indeed, everyone knew before, since the great mass of illustrations on which physicians have based their theories upon this matter are necessarily drawn from among (relatively) uneducated women, since the number of women who have received anything like a complete education is as yet very small.

Will you allow me to note two points, which seem to me to have been overlooked in this discussion, exhaustive as it apparently seemed to be?

1st. It seems to me a singular exaggeration to assume

that the course of study at any existing American college, academic or professional, involves a serious wear and tear on the nervous system, or any very strenuous brain action. The work consists not in independent and original intellectual effort, but simply in the acquisition, step by step, of a definite amount of information. For anyone who has taken all the preceding steps, such acquisition of new knowledge can cost no serious exertion. It is as easy to go from the nineteenth to the twentieth step, as from the fourth to the fifth.

It would not be difficult to show that there would be more risk to health in sitting for six hours every day doing nothing, than in spending six hours out of the twenty-four (not necessarily at one session) in reading Latin and Greek books. It is evident that when these languages are understood, it is not more difficult to read them than English or French; and until they are understood the books are not read, but a much more elementary mental process than reading is carried on.

It seems to me that college-bred men who, since leaving college, have engaged in the intense activities of original scientific researches, or been immersed in the intense anxieties of responsible medical practice, should be the first to recognize the radical differences which exist between such brain-work and the moderate intellectual exertion involved in simply acquiring the current standard of knowledge in the classics, or in mathematics, or in an ordinary medical curriculum. But this moderate mental exertion—appropriate, it is true, to immature youths—is habitually referred to, in these discussions, as if it implied the labors of Newton and Bacon combined. A fixed standard of measure is essential to accurate discussion, but it is habitually neglected.

2d. Again, in these discussions, mental activity is constantly described as a pure expenditure of force, and the influence of the active brain in regulating and harmonizing the nutritive processes of the entire organism, is insufficiently recognized. In the symposium, this influence seems at first sight to have been admitted by several writers. But the assumption is nevertheless maintained by all, that brain activity is a pure expenditure, that the menstrual process is another pure expenditure; hence, if the two go on together, the organism must become bankrupt. If the above and widely accepted proposition were true, no woman would be capable, I will not say of university education, but of any life more arduous than that of Eastern harems. The obvious fact that the great mass of women, as of men, do and always have led arduous lives, should be accepted as a *reductio ad absurdum* of the doctrine, because, as I have shown in my *Essay on Menstruation*, the essential menstrual process covers not one week, but more than three out of every month—more than three-quarters of the adult woman's life until the menopause. But this process, so far from being an exhausting one, seems to constitute the fundamental nutritive stimulus to the female organization. Loss of such stimulus is severely felt, as shown in cases of functional amenorrhœa, and often in patients from whom the ovaries have been removed. Though relieved, possibly, of the intolerable suffering of dysmenorrhœa, the nervous system of such patients seems to remain, at least for a long time, out of equilibrium—in a state of atony, if I may so express it. If the menstrual process were a pure expenditure, pure waste of force, the latter individuals should rather be expected to reach exceptional degrees of vigor, which is certainly never the case, even when restoration to health is most complete.

But I have shown, and others have since repeated my experiments with the same results, that the supplementary wane of nutrition contingent upon the menstrual process, suffices and more than suffices to cover its expenditures. The greater reproduction cycle of pregnancy involves a still more painful wane of supplementary nutrition, whose details are easily recognizable. The nutriment for both these wanes is saved from the muscular nutrition of the female organization, which is universally, and constantly, and conspicuously inferior to that of the other sex. The women who, apart from actual uterine disease, are seriously disturbed at menstruation, are women with a distinct neurotic taint. Menstrual disturbance may properly be classed among the hysterical stigmata, and, like the others, implies deficient cerebral control over lower nerve centres.

It is well understood that cortical activity increases cerebral control, as distinctly as, in the famous experiment, the crystal of chloride of sodium laid on the optic lobes of the frog inhibited the reflexes of the spinal cord. It might, therefore, be anticipated that increased cortical activity, the correlative of increased mental exertion, would tend to remedy the disorders resulting from an ill-regulated action of lower nerve centres, among those controlling the pelvic circulation and innervation; possibly, also, the mysterious nutritive processes lying at the very basis of the menstrual functions. As a matter of fact, this is seen to be the case over and over again, whenever the observation is sought for; as positively as dysmenorrhœa, and even organic uterine disease, is liable to originate in emotional excitement—so positively does purely intellectual work—unalloyed by care or anxiety correct such disturbance, so that dysmenorrhœa tends to disappear under its influence.

If the neurotic taint be profound, the foregoing proposition may not prove true. Yet even in cases of serious hysteria—where the (so-called) menstrual week was liable to be attended with more or less irritability of temper—and to necessitate avoidance of physical exertion, I have not unfrequently found that college-bred women were in nowise incapacitated for their habitual mental exertion, whatever that might be, and it was frequently of a literary character.

I claim that the assumption of special mental incapacity during the menstrual period is entirely false as regards the great majority of women; certainly of women who would be engaged in intellectual pursuits; certainly of girls at the age for going to college—in which it may still be presumed that uterine disease is not yet developed. It has never yet been shown that the habit of continuing the college studies during the menstrual week is really the cause of ill health even in those who break down. For this condition has never yet been eliminated from the others with which it is always associated, and any one of which would be sufficient to cause ill health, and does so in girls who never dream of college at all.

When it is said that an observant physician can always distinguish a difference in the nervous condition of a woman at the menstrual period, it is not stated whether this observation is confined to the nervous women who populate the hospitals, or whether it is seriously claimed for observations of the feminine world at large. In the

first case, it is, of course, true; in the second it certainly is not. But even where such an observation would hold good, it is of an entirely different nervous sphere from the intellectual. Undoubtedly there are women who become perceptibly more irritable, more unreasonable, more emotional at the menstrual period; whose senses are more acute, so that they are more easily annoyed by noises or smells; who are more fanciful, more easily depressed, who may even be habitually and causelessly depressed at such times. But all these changes—which are very far from being universal even among rather delicate women, and are absent altogether in the robust—do not necessarily affect the power of attention, or of application, or of appreciation of a subject presented to the intellect. Whether or not the power of original work is affected would be an interesting subject of inquiry, but assuredly no data as yet exist upon which it might be made. It is physical exertion that needs to be diminished, when that is practicable, as it only is in certain favored classes of women; it is emotional excitement, the occurrence of which can never be foreseen, that should be averted from the period of the menstrual flux.

Perhaps it is because of the recognized impracticability of these precautions in the immense majority of cases that women's advisers turn to mental occupations as the one thing which may be denounced. Yet it is in reality the principal thing which for healthy women it is desirable to leave unchanged.

Whatever other arguments may be urged against co-education, it seems to me that one at least is quite unsupported by evidence, namely, that which assumes a periodical incapacity of women to perform mental work, which incapacity is supposed to become greater and more injurious the more the woman herself is unconscious of it; which, in fact, is most conspicuous when absent, and most fatal when the woman student is able to disregard it entirely—as to maintain our record of attendance unbroken, and to keep a high standing in a class of young men!

It may be added that the further assumption that collegiate work proper ever involves a strain upon those who have been suitably prepared for it is equally unproven.

MARY PUTNAM JACOBI.

CO-EDUCATION AND THE HIGHER EDUCATION OF WOMEN.

To the Editor of THE MEDICAL NEWS,

SIR: The symposium on "Co-education and the Higher Education of Women" in your issue of December 14, 1889, might have been more complete if it had contained the opinions of medical women. In deliberations concerning the health of women, women physicians, because they *are* women, have opportunities for forming correct opinions that men cannot have. The latter know chiefly the sick and invalid class, and arrive at conclusions in accordance with this knowledge, whereas women physicians know intimately their well and their sick sisters.

I know that space is necessarily limited in a periodical like yours, but I think there are a few points not sufficiently brought out, and some conclusions reached that seem to me mistaken. Of these I would like as briefly as possible to speak.

One author, after citing the showing of Dr. Mary Putnam Jacobi that "46 per cent. of women suffer more or less at menstruation," says: "It is evident that in a system of co-education women are handicapped by the manifest necessity of abstaining from severe or sustained mental work for several days in every month."

I do not see that the conclusion is a logical necessity. Let the remaining 50 per cent. and over who do not suffer seek the higher education if they wish. The eminent doctor seems to think that at least the majority are affected in this way, but he does not show that such is the case. On the contrary, plenty of women can be found everywhere, who have borne children, too, who tell us that they have never experienced ill feelings during their menstrual periods.

Of the 46 per cent. who say they suffer, it is not shown that their disabilities are sufficient to make it necessary for them to abstain even one day from their daily avocations, whether of "severe" and "sustained mental work," or other arduous work.

Another physician says: "Let us compare the average male student with the average female student. Let us consider that she has for several days in every lunar month to forego her daily bath, to curtail her customary exercise," etc. Why does she need "to forego her daily bath?" Is it for the same reason for which, not many years ago, a lying-in woman was required to remain in her bed nine days without a drop of water being applied to her person? One is often met even yet by remnants of superstitions as regards the injurious effects of water used either externally or internally, and what appears like superstition should not proceed from the pen of a great physician and author. I can refer any who may be interested to several women who have not only personally used baths at all times of the month, but have prescribed the same to patients for years, with no ill effects in either case.

As to "curtailing her daily exercises," if he means by that her daily occupation, he is wrong, for the majority of women belong to the industrial classes, who have no idle days. If he means the cultivation of her muscle, he may be in a measure right, but it is not shown that intellectual ability and muscular development are often associated in the same person. It sounds thoughtful and gallant in men to appreciate woman's disabilities and burdens, and to oppose anything arduous for her, but it remains to be seen that they correctly understand the best way of making life of more value to her. It is certain that the effort to relieve women of onerous duties has always been a failure for the great mass. "Prolonged confinement" and "prolonged brain-work" in various directions are certainly very common.

When a woman does not shrink from an arduous life, and looks forward to it from necessity or choice, and would better herself and her opportunities by higher education, she is met at once by disagreement from one of the best informed and most philanthropic class of citizens—the doctors. They tell her it is impossible. She cannot be equal to the labors and honors of brain-work. If she tries she will become a victim of neurasthenia, and in case she is not already a mother, she will probably be deprived of happy maternity.

They do not stop there, but say it would be immodest for her to put herself where men could observe her at her daily work in her laboratory, recitation or lecture-room,

and see and possibly understand the disabilities she would be sure to have.

In the first place, women are not as frail as physicians are sometimes led to think; and in the second, strength comes by the demand made for it. As with the young man, when he acquires manhood's motives for constant labor and puts out his strength he surpasses in deeds those of his boyhood, so with the woman, an aim, a purpose, as, for instance, the study of medicine, checks any emotional and hysterical tendencies, and from a nervous invalid she often becomes strong and vigorous. A weakly wife is left a widow, and, added to her deep grief, she not seldom attends to her family and to her husband's business as well, so that both prosper, and she knows nothing of her previous physical infirmities.

As to competition working more injuriously to women in co-educational institutions than in those for women alone, observation seems to indicate that it is the system of education that is at fault, and that competition is as fierce where there are women alone as it is possible to be anywhere.

It would be interesting if we had statistics comparing the health of women at co-educational institutions with that of those at woman's colleges. The menstrual difficulties, so often observed at girls' boarding schools, according to my observation and experience at Cornell are almost unheard-of. The average non-attendance from class exercises of the young women from the cause of ill health, compared with that of the young men students from the same cause, showed a proportion in favor of the young women. Those I have known from co-educational institutions have given similar reports in this matter.

Probably in women's colleges it is not the fact that the education there is either "prolonged" or "severe" that causes the ill health noticed. In the institutions of best standing there is no more suffering reported than in those of more superficial instruction. My opinion is that in all of these, one factor causing deterioration of health is the unnatural social circumstances in which a young woman finds herself placed. Her liberties are largely restricted, and she has not the ordinary association of both sexes to which she has always been accustomed in her home. This I consider a potent factor in the frequent decline of woman's good health in women's colleges.

At Cornell I have never heard that there was any occasion for a "masculine smile," which one of the authors so feelingly mentions as an objection.

I cannot imagine a "masculine smile" being called forth there by the absence of a young woman from her work several days each month. Such disabilities would be felt to be out of place at an institution where hard work was expected every day, and such a one would before long find herself weeded out at examinations and allowed to go home where the men about her might smile or fret at the ill health of their families.

As to the higher education interfering with child-bearing, it would be interesting to follow a line of investigation to ascertain whether in men higher education was not prejudicial to the production of large families. I think, however, the popular belief is the correct one, that the shanties of the ignorant and poor show the greatest number of children. If, as Napoleon told Madame de Stael, the greatest woman is she who bears the most children, then both education and all the advantages and refinements of civilization should alike be avoided.

Woman's dress has been alluded to, very justly, as a hindrance to her complete development in any direction. I think, however, the advance made in this line has been in keeping with that made in her higher education. In proof of this I will cite the present demand for "common sense" shoes and under-waists, for warm flannel underclothing and suspended garments, and looser dressing, which means larger waists. The gymnastic dress is worn for mountain-climbing and other out-of-door exercises. Women no longer think it praiseworthy to be dressed dolls in the parlor and to subsist on but little of the daintiest fare. On the contrary, they take pride in their athletic feats; the mountains they have climbed, their success at tennis, their skill in managing oars, in swimming, in being good horsewomen, etc. In many places the women as well as the men are making constant use of the bicycle.

I may as well mention one point that has not been touched where women have the advantage of men in co-educational schools. The young man attending the best of our colleges are picked men from the localities from which they come. The average college morality in this country is high, and pains are taken by all college authorities to keep it so, but women know no such voluntary expenditure of force and vitality as is caused by the habits of wine-drinking, tobacco-using, and social vice. These, to say the least, are never uncommon in any large gathering of men, though it is said to be much less so in co-educational institutions than in others.

MINERVA PALMER, M.D.

ROCHESTER, N. Y.

NOTES ON INFLUENZA.

To the Editor of THE MEDICAL NEWS,

SIR: The following notes from this locality, in connection with the epidemic of catarrhal fever now prevalent, may be of interest.

During the past half year the humidity, temperature and rainfall have been above the averages. There has been an unusual amount of urticaria in both sexes and all ages, and various forms of erythema, especially in children. In the autumn muscular rheumatism and bronchitis prevailed, and later, pharyngitis and tonsillitis were frequent.

In many cases of children, influenza has simulated scarlet fever. Ushered in by vomiting, slight sore throat, and anorexia, and followed within forty-eight hours by a scarlet eruption, commencing upon the chest and spreading over the body; tongue coated, papillæ enlarged; the conjunctivæ often a bright scarlet. The fever is not high; the pulse but slightly accelerated; the throat symptoms are slight; bowels normal. In the adult, the raging head-ache, back-ache, vertigo and inflammation of throat and bronchial tubes are the chief symptoms.

Sponging, followed by inunctions to the skin, and aconite internally act satisfactorily with children. Phenacetin, antipyrin, or antifebrin quickly relieves the neuralgic pains. Salicylate of sodium or quinine controlled the muscular symptoms. The coryza is checked by atropine or tincture of belladonna. The dry, "stuffy"

feeling of the nasal passages yields to potassium iodide, and the bronchitis to a combination of ammonium bromide and potassium iodide. The above treatment has given the best results in the cases under observation. The duration is short and termination favorable, and symptomatic treatment seems to be all that is required.

M. S. SIMPSON.

PLAINFIELD, NEW JERSEY.

NEWS ITEMS.

Smallpox Imported in Egyptian Rags.—At the Seymour Paper Mill, Windsor Locks, Connecticut, smallpox has been reported. Two out of the eighty females employed in the rag-sorting room are down with the disease. Egyptian rags are said to be the commodity handled by the persons who took the disease, and yet the mill proprietors assert that a thorough disinfection was reported before the goods were allowed to land.

Atropine Dispensed for Antipyrin.—At the town of Gouverneur, N. Y., a life was recently lost in consequence of dispensing atropine for antipyrin. A citizen of prominence and worth at that place prescribed for himself a five-grain dose of the latter, for the relief of neuralgia. The person in charge of the drug-store sold him five grains of atropine, which was taken soon afterward, and resulted fatally about two hours later.

The Earl Crematory at Troy, New York.—The twelfth crematory erected in this country has just been finished at the Oakwood Cemetery, Troy, New York. Two bodies have already been incinerated there. This is, without doubt, the most elaborate structure of its kind in the world, comprising, as it does, a chapel and lofty tower, besides the furnaces. The chapel stands in memory of the late Mr. Gardner Earl, having been presented to the cemetery by members of his family. The structure, as a whole, will bear the name of the Earl Memorial Building, but will be free to the use of those who have the privileges of the cemetery.

The New York Hospital Sunday Fund.—The collections under the Saturday and Sunday Hospital Fund, New York City, last year have, as far as reported, amounted to $46,000. The Executive Committee has just issued a card calling upon the donors to the fund to renew their contributions, on account of the extraordinary demands made upon the hospitals by the epidemic of influenza. The various charitable institutions are crowded and strained to the utmost, both for means and room, and the pressure must continue for some time to come, involving a large additional and unexpected expense. The prevailing epidemic will about double the expenditures of some of the hospitals during the winter quarter.

The Prevention of Leprosy.—The Surgeon-General has issued a circular to medical officers of the Marine-Hospital Service and to collectors of ports calling attention to the prevalence of leprosy in several foreign countries, and promulgating regulations for the protection of the people of the United States from the disease.

Surgeon T. H. Parke Honored.—Surgeon Parke, of the British Army, the companion of Stanley in his three years' walk across Africa, has been made an honorary Fellow of the Royal College of Surgeons of Ireland. A movement is on foot among the medical men of London to give him a testimonial dinner when he reaches that city. A recent cable dispatch reports that the health of Surgeon Parke has improved since his arrival at the East Coast, and that he will be on his way homeward within a month.

Execution by Electricity.—A committee, composed in part of physicians—Drs. C. F. Macdonald and A. D. Rockwell—and in part of electrical experts, has been testing the dynamos that are to be used in New York State for the execution of criminals. These machines have been found to deliver a voltage considerably in excess of what was demanded or expected from them. When run at ordinary speed a pressure of 1600 volts was obtained. With 300 revolutions per second the pressure would probably exceed 2000 volts, a lethal energy which will explain many of the recent tragical accidents reported from various parts of the country as due to the electrical lighting currents.

The Value of a City's Refuse.—The value of the refuse of a great city is seen in the fact that the New York Street Commissioner has given a contract to trim the garbage scows to an Italian, who agrees to pay the city $1552 per week for the privilege, or $80,704 yearly. The privilege was sold last year for $1101 per week. The contractor employs men to pick over the refuse while trimming the scows, and from what they hand over to him he is able to secure a large profit.

Ambulances for Chicago.—Through the instrumentality of a woman, an ambulance was presented to the mayor and citizens of Chicago during Christmas week. This ambulance was subscribed for by private individuals, and will be used experimentally at first in the expectation that others will be added, and, by degrees, be substituted for the police patrol wagons. If the plan succeeds, there will eventually be a complete ambulance system for the whole city, under the control of the surgical staff of the police department.

Indian Medicines.—Every one is more or less familiar with the expression "a good Indian medicine," as referring to some indigenous herb. In a recent lecture by Major J. W. Powell, Superintendent of the United States Geological Survey, it was pointed out that this is an incorrect use of words. To the Indian mind there is no medicine except sorcery. The idea of remedial power in any herb or other substance is foreign to the mind of the red man, who is very tenacious of his belief in witchcraft. The "medicine-man" is a sorcerer and priest, rather than an adept in the healing art; he, therefore, does not recognize "a good medicine" in the sense of a useful medicament.

The President of the American Society of Naturalists.—Dr. H. Newell Martin, of the Johns Hopkins University, has been elected President of the American Society of Naturalists.

Explosion of a Bottle of Carbonated Water.—A nurse at the German Hospital, New York City, was recently injured by the explosion of a bottle of carbonated water. One eye was destroyed, and the other so seriously damaged that she may become totally blind.

Obituary.—Dr. William Oswell Livingstone died at St. Albans, England, December 30th, the last-surviving son of the great African explorer, Dr. David Livingstone. He was born in Africa thirty-nine years ago, and was educated at the University of Glasgow. He formerly practised medicine at Port of Spain, Trinidad, W. I. For the past nine years, on account of feeble health, he had not been in practice. A small pension was granted him by the British government.

Death of Dr. Thomas T. Minor.—Dr. Thomas T. Minor, of Seattle, Washington Territory, formerly Mayor of that city, and member of the Constitutional Convention, is supposed to have been drowned. He was one of a hunting party which was expected to return to Seattle about December 5th. An empty and adrift canoe has been found belonging to the party, and no other tidings.

Newly Elected Officers of the New York Pathological Society.—At an election held on January 8th the following officers were elected:

President.—J. West Roosevelt, M.D.
Vice-President.—H. P. Loomis, M.D.
Treasurer.—J. H. Hinton, M.D.
Secretary.—Thomas L. Stedman, M.D.
Editor.—George C. Freeborn, M.D.
Committee on Publication.—T. Mitchell Prudden, M.D., and Walter B. James, M.D.
Committee on Admission and Ethics.—W. P. Northrup, M.D.; R. H. Sayre, M.D.; H. P. Loomis, M.D.; Ira Van Giesen, M.D., and John S. Ely, M.D.

Typhoid Fever in Berks County.—Typhoid fever is said to be endemic in Berks County, Pa.

Guy's Hospital Gymnasium.—Dr. F. W. Pavy has introduced a rather novel proposition, to the medical circles of London, in an offer to present to the College at Guy's Hospital a gymnasium for medical students.

The Ophthalmic Review.—The *Ophthalmic Review* begins its new volume with an American editor, Dr. Edward Jackson, of Philadelphia, who succeeds Dr. James Anderson, of London. It will hereafter contain original articles from American as well as English ophthalmic surgeons, with notices and full reviews of ophthalmological papers published in this country and abroad.

The Hyderabad Chloroform Commission.—A telegram to the *Lancet*, from Dr. Lauder Brunton, states that after experiments on four hundred and ninety animals he has reached the conclusion that the danger of chloroform is asphyxia, not heart failure—a direct reversal of Dr. Brunton's former views.

A Coroner's Fee Lost.—Dr. A. T. Weston, Deputy Coroner of New York, was called on December 20th to make the preliminary medical inspection of a child reported for inquest by a midwife. Twins had been born to a German woman on the 18th, one of them dying soon after birth, the second lingered nearly two days: such was the report of the woman. When Dr. Weston saw the child he suspected a spark of life remained within it, and in the course of half an hour or more he had the satisfaction of resuscitating the child. Some years ago, it is stated, a supposed dead baby reached the Morgue before the fact of remaining vitality was discovered.

Antipyrin in Sea-sickness.—Surgeon George B. Parsons, of the "Ocean" steamship line, has had a limited experience with antipyrin in *mal de mer*, which leads him to prefer it to the bromides, chloral, nitrite of amyl, and cocaine. In the *Provincial Medical Journal* for October he summarizes his results in twenty cases: twelve escaped entirely; the other eight suffered less than on previous voyages. He gives five grains on embarking and repeats the dose in four hours. As a rule, three doses at most are required. In very severe cases, he would give the antipyrin hypodermically, and apply counter-irritants to the epigastrium.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING JANUARY 11, 1890.

WHITING, ROBERT, *Passed Assistant Surgeon.*—Detached from the "Minnesota," and ordered to the "Dale."

PICKRELL, GEORGE MCC., *Assistant Surgeon.*—Detached from the "Dale," and ordered to the "Minnesota."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 7 TO JANUARY 13, 1890.

By direction of the President, LEONARD Y. LORING, *Major and Surgeon*, will report in person to Colonel Benjamin H. Grierson, Tenth Cavalry, President of the Army Retiring Board at Los Angeles, California.—Par. 3, *S. O. 6, A. G. O.*, January 8, 1890.

By direction of the Secretary of War, leave of absence for six months, on surgeon's certificate of disability, with permission to go beyond sea, is granted LOUIS M. MAUS, *Captain and Assistant Surgeon.*—Par. 13, *S. O. 4, A. G. O.*, January 6, 1890.

WALKER, FREEMAN V., *First Lieutenant and Assistant Surgeon* (Jackson Barracks, Louisiana).—Is granted leave of absence for one month, on surgeon's certificate of disability.—Par. 7, *S. O. 5, Division of the Atlantic*, January 7, 1890.

By direction of the Secretary of War, R. B. BENHAM, *Captain and Assistant Surgeon*, is relieved from duty in the Department of the Platte, to take effect upon the abandonment of Fort Laramie, Wyoming Territory, and will then report to the commanding officer at Madison Barracks, New York, for duty at that station.—Par. 8, *S. O. 6, A. G. O.*, January 8, 1890.

BLACK, CHARLES S., *Captain and Assistant Surgeon.*—The leave of absence for seven days, granted by the commanding officer Fort Du Chesne, Utah Territory, is hereby extended twenty-three days, with permission to apply to the Adjutant-General of the Army for an extension of three months.—Par. 3, *S. O. 1, Department of the Platte*, January 1, 1890.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

ORIGINAL LECTURES.

RADICAL OPERATION FOR HERNIA.

Abstract of a Clinical Lecture
Delivered at the Harlem Hospital, New York.

BY THOMAS H. MANLEY, M.D.,
OF NEW YORK.

THE first case presented for operation was one of strangulated inguinal hernia. The patient, a strong man of twenty-four years, gave a history of having noticed a swelling, in the left side since he was six or seven years old. He had worn a truss almost continuously until two years ago, when he found that after having left it off the hernia did not reappear.

The features in the clinical history to which Dr. Manley particularly directed attention were, first, the origin of the trouble. The patient thought that the hernia had not appeared before he was seven years old; but Dr. Manley was convinced that while the protrusion may not have been large enough to attract notice until that age, the lesion was congenital, as are the vast majority of all herniæ.

Secondly, the patient, supposing himself cured, had discarded the truss for two years; and it was only after a severe strain that he found his rupture had returned. For the first time he found that after patient and persevering efforts he could not reduce the hernia.

It descended at about three o'clock in the afternoon. Two hours later a local practitioner was summoned, but failed to reduce it. Constitutional symptoms having developed, the patient was advised to seek admission to hospital.

The great pain at the seat of the protrusion, which was very large, and the constant vomiting and great exhaustion, all pointed to strangulation.

The operator said he approached the case with two objects in view. The first and most important was to relieve the obstruction by dividing the constricting band wherever it might be located; then to complete the operation with the object of a radical cure of the hernia.

Here he referred to the defective structural development; the deranged and confused anatomical position of the parts; which should be considered before deciding on the precise surgical measures which might prove most efficient in obtaining a cure.

Important questions were:

Did the fœtal type still persist?

Was there an undescended testicle or one lying somewhere in the inguinal canal, or, further, if the testicle had descended, was it adherent to the floating viscera of the abdomen, carrying a portion of them to the base of the scrotum?

Was the fault due to an excessive amount of omentum or an abnormally long mesenteric ligament?

The operation was begun by the long, free incision. On reaching the deeper structures it was at once manifest that the case was one of the congenital variety. There was no true sac. The immense mass of extruded omentum lay in apposition to the tunica albuginea of the testicle, but was not adherent to it.

On finding this condition Dr. Manley stated that he would be unable to do the classic operation of McBurney, which he had hitherto performed with most gratifying results in strangulated hernia. He would do a modified Macewen operation, or what might, perhaps, be designated a "McBurney-Macewen operation." He would ligate the sac off without sacrificing the testicle, and fill in and obliterate the greatly enlarged space between the pillars of the ring.

In order to do this, after ligating and cutting away the superfluous omentum, the remaining stump was fixed in the canal with the quilted suture, after the plan of Macewen, while the remainder of the operation was completed after the McBurney method—the cutaneous margins of the wound sewed down to the peritoneum—and the whole treated by the open method.

The second case for operation was a boy of seven, who had had his hernia since birth. His father had taken him to travelling charlatans during the first few years of his life, but lately had consulted several well-known surgeons. There was a great difference of opinion as to what the swelling really was, and as to the plan of treatment; some maintaining that it was a hydrocele or an encysted spermatocele, etc.; some recommended operation and others advised against it.

There were a few points unmistakably clear in connection with this case. The first was, that there was a protrusion that increased in size with the boy's growth, and that could not be reduced. Again, its growth was rapid, and it became so prominent, under the trowsers, that it attracted notice, and hence brought down on the lad the jeers and banter of other boys, so that the little fellow himself was anxious to get rid of it.

Thorough antisepsis being observed, the operation was commenced with the usual long, free incision over the line of the spermatic cord, from the internal ring downward. Here, as in the preceding case, there was no sac, but after freely opening the tunica vaginalis, which invested the protruded mass, it could not be replaced in the abdomen with ordinary taxis. The enlargement consisted of nearly twelve inches of intestine. It was found, on careful examination, that the reason the gut failed to return was not resistance from above, but because on its mesenteric border the vas deferens, the epididymis, and testicle were in one confused mass, all bound rigidly to the intestine by organized fibrous tissue, which had to be divided with the scissors.

After having thoroughly freed the bowel, the atrophied testicle was removed high up, when the gut itself was returned and the peritoneal cavity closed, by ligating

off the fascia propria on a line with the internal ring. The wound was treated by the open method.

Dr. Manley next exhibited a man, seventy-three years of age, on whom he had operated successfully three months previously.

The man had a large incarcerated hernia on each side, which, he said, had annoyed him for more than forty years. At first they were reducible, but owing to badly fitting trusses a localized peritonitis had developed, which ended in the firm adhesion of the sac to its contents; and had, in this instance, as is usually the case in all after a sufficient time, produced what is known as incarcerated hernia.

Dr. Manley asked that the great difference in age be noticed in these two cases, and said that neither extreme constituted an obstacle to operative measures, if the patient was in sound health. On the other hand, in congenital hernia he would advise the operation at the earliest possible date; preferably before the infant was a month old.

NOTE.—The two cases operated upon made excellent recoveries, and were dismissed from the hospital, cured, six weeks later.

GENERAL OBSERVATIONS ON THE USE OF ELECTRICITY IN GYNECOLOGY.[1]

BY A. D. ROCKWELL, A.M., M.D.,
PROFESSOR OF ELECTRO-THERAPEUTICS AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

UNTIL a recent period the advances in the therapeutic uses of electricity were more especially along the line of those distinctively nervous affections that were neither specific nor structural in their nature. Cases of this latter type have always yielded but meagre results under electrical treatment, and I do not know that any competent authority seriously claims for electricity in most cases of structural disease of the central or peripheral nervous system, more than temporary and palliative effects. And yet those who, arguing on the side of their prejudices, or out of the fulness of their ignorance of the subject, ascribe to electricity a very low place in therapeutics, do so mainly on the basis of its failure to cure a class of conditions incurable by any method of treatment.

The statement that as a therapeutic agent "the effects of electricity are limited," must indeed seem a rash observation to those who have had repeated evidence of the wide range of its influence in the relief of nervous symptoms, and especially so to those who have witnessed the really remarkable relief so often afforded by intra-uterine applications of the galvanic current. When a man possessed of the experience of Keith, of Edinburgh, can say that many are prejudiced against electricity because they consider it quackery and know nothing about it; that his confidence in its power to relieve disturbing symptoms of uterine fibroids and to cure many chronic inflammatory conditions of the pelvis, continues to increase, and that he has no fear for the future of electricity, we have testimony that must greatly outweigh assertions and opinions that are purely negative.

In a recent and animated discussion of the subject at the Société de Chirurgie of Paris, equally favorable opinions were advocated by the majority of those engaged in the debate, and the strength of these opinions was accentuated by the fact that the majority of those who hold them are signally distinguished as laparotomists.

I do not propose here so much to give the results of my own experience in gynecological electrotherapeutics as to allude, and very briefly, to some points in the rationale of its effects.

I call attention first to the faradic current. Its effects are mainly mechanical, and according to the construction of the helix and the length and thickness of the wire do we measure its action on the muscular tissues of the uterus. Applied directly to the uterus of animals in physiological experiments, the organ visibly contracts, although not to such an extent as the intestines, which, on application of the electrodes, can be seen to draw up gradually very much after the manner of a woman's work-bag. Its action on the smooth muscular fibres of the human uterus, when applied therapeutically is analogous to that of ergot, although manifestly more prompt and energetic, especially under the influence of the positive pole, which possesses a much greater power over the involuntary muscles than the negative. It is a current of alternation, of constant closing and breaking, hence it produces a sort of interstitial massage, heightening the activity of the circulation, accelerating absorptive processes, and influencing favorably the nutrition of parts.

Faradization, by its power over muscular contractions, sensibly increases temperature. According to the chemistry of the development of heat during muscular contractions, muscular work is the result of the decomposition of nitrogenous substances, and the muscles grow at the same time that they work and develop heat. That the value of the faradic current is more limited than the galvanic in the treatment of uterine disease must be immediately manifest to all who appreciate the difference between them, but in some conditions which come within the range of its physical and physiological activities, the faradic current may exceed in efficiency the galvanic. By its direct excitation of the smooth muscular fibres of the uterus we are enabled to combat that stasis of the circulation which is the beginning of uterine inflammation.

By this method we obtain a veritable interstitial

[1] Read before the New York Academy of Medicine, Section in Obstetrics and Gynecology, November 27, 1889.

massage that is potent in overcoming the primary inertia of the organ, and in preventing an arrest of retrograde metamorphosis, through which comes sub-involution with its inevitable and persistent sequelæ. In its purely local influence, then, faradization would seem to be preventive rather than curative, as it relates to uterine disease; or rather it is preventive so far as concerns the latter condition of uterine engorgement, and curative only in its initial stage. When the processes that go to make up the graver and more chronic diseases of the uterine parenchyma and its lining membrane have continued a long time, as is usually the case when medical interference is sought, the simple mechanical effects of the faradic current would be altogether misdirected.

Here we resort to the electrolytic influence of the galvanic current, or rather to what may be more fitly termed its galvano-chemical cauterizing effects through which are destroyed the granulations and fungoid growths of the diseased mucous membrane. By the interpolar influence of the current we correct a languid nutrition and hasten the absorption of exudations.

Just as the positive pole of the faradic current has an action of its own, superior in effect to the negative in causing uterine contractions, so the positive pole of the galvanic current has an action peculiar to itself. Here oxygen is generated and acids accumulate, which render this pole directly hæmostatic. It is, therefore, indicated in all hemorrhagic conditions, as well as where there exists an excess of the natural secretions. Owing, also, to the greater retractibility of cicatrices following positive galvanocauterization, the results are more lasting in the treatment of fungoid growths, or vegetations, than could possibly be the case with the negative pole.

At the negative pole, on the contrary, the alkalies precipitate, imparting caustic properties and causing effects fluidifying rather than hæmostatic. The absorptive process is undoubtedly more active under this pole than under the positive, and is especially indicated in indurated chronic metritis and for the resolution of fibroids.

That the galvanic current often completely dissipates fibroid tumors of the uterus few will, I believe, affirm. In the treatment of scores of fibroids on the external surface of the body, I have never yet seen a single instance where one of them completely disappeared. As a rule, the reduction is comparatively slight, unless suppuration is excited, which may be easily done. External fibroids are simply unsightly, and for this reason we desire to be rid of them, and as it is not possible to obtain more than a reduction in size, the knife is to be preferred, and electrolysis has fallen into disuse. We treat uterine fibroids, on the contrary, not because they are unsightly, but because associated with them are a train of symptoms sometimes of the most distressing character. These symptoms can, it is believed, be relieved to a greater or less extent by electrolysis, and sometimes so completely relieved as to lead to the belief, so far as the patient is concerned, that the tumor has entirely disappeared. In the great majority of cases, however, it is simply a symptomatic cure. The tumor is still there, but reduced in size, and so far as pressure upon surrounding parts is concerned, or any hemorrhagic tendency, is entirely harmless. I am a firm believer in the great utility of the galvanic current in the thickenings and infiltrations resulting from inflammation of the pelvic cellular tissue. For the absorption of old exudations in other parts of the body, this treatment has long been used with excellent results, and in pelvic exudations the results are even better. I have seen the treatment, persistently carried out, result not only in the absorption of large pelvic deposits, but in the cure of the most obstinate and severe sciatica, and in the restoration of power to partially paralyzed limbs. In such cases, both sciatica and paralysis are caused, undoubtedly, by pressure upon the pelvic floor, and can be relieved only through the dissipation of the morbid products.

There are two methods of action through which we obtain results from electrolysis. The first and most apparent is the absolute destruction of tissue which takes place at the time of treatment. Some suppuration may follow, and thus, by an actual loss of substance apparent to the sight, the tumor decreases in size. If, however, these were the only active forces in the electrolytic process, the method would lose much of its effectiveness.

If this be not so, how can we account for the many well-attested cases where morbid growths have entirely disappeared under simple external applications? Herein is the difference between the electrolysis of organic and inorganic substances. In the electrolysis of inorganic substances the effects cease as soon as the current ceases, the substances remaining in the condition that the current left them. The electrolysis of organic substances, on the contrary, starts a process that continues long after the current ceases to flow. Beside this subsequent effect, the current penetrates the tissue and induces various important changes beyond and beneath the eschar, and these combined agencies do far more, in many cases, to diminish the size of morbid growths and prevent further development than an actual destruction of a limited area.

A word in regard to the use of electricity for the relief of pain. No one can deny the excellent results that frequently follow the application of the galvanic and, indeed, of either current in uterine and ovarian pain, and as a somewhat extraordinary

illustration of this I beg, in conclusion, to relate briefly a single case:

The patient was a married woman, aged thirty, and was referred to me, March 15, 1886, by Dr. J. O. Farrington, of this city, under whose care she had been for some time. She sought relief for pains in the ovarian region that were not only excessive, but most persistent, in spite of all efforts for her relief—including extirpation of both ovaries.

She had suffered more or less at each menstrual period for six or seven years, but for two years previous to the operation to which she had submitted, the pain had been so agonizing as to render her life absolutely unendurable. While the menstruation was scanty, it was nevertheless always on time, and continued during a period of nearly two weeks in a halting, irregular manner and with few intermissions. Everything attempted for her relief having failed, it was proposed to remove both ovaries, a proposition to which the patient eagerly consented, and, on the 3d of July, 1884, the operation was successfully performed by Dr. T. G. Thomas.

To the concern of all interested, however, the periodical appearance of blood still continued to some extent, associated with pains less acute, but still of a severe type.

The flow gradually disappeared, but the pains increased, coming on at regular intervals until, at the end of nine months, they were quite as distressing as at any previous time, and so continued until I saw her, through the kindness of Dr. Farrington, about a year subsequently. Under internal applications of the galvanic current, varying from twenty-five to fifty milliampères in strength, the paroxysms began to yield rapidly, resulting in a few months in a complete and what has been demonstrated a permanent recovery, for in the three years that have elapsed since the treatment was discontinued there has been no return of pain.

A very important practical question must immediately suggest itself to every one who reads the account of this case, as it did to the patient herself. If the treatment by the galvanic current had been attempted first instead of last, would it have been necessary to perform the formidable operation that she underwent?

While I cannot presume to answer this question, it is self-evident that an agent like the galvanic current, possessing such a marked influence over so many forms of pain of obscure origin, should precede rather than follow severe operative procedures for their relief.

THE TREATMENT OF CERTAIN PELVIC TUMORS BY GALVANO-PUNCTURE, DRAINAGE BY THE VAGINA, AND INTRA-UTERINE GALVANIZATION.[1]

BY AUGUSTIN H. GOELET, M.D.,
OF NEW YORK.

I DESIRE to be understood, in the beginning, as referring only to such tumors as are easily accessible by the vagina for galvano-puncture, and to those which are so intimately associated or connected with the uterus as to be influenced by the chemical galvano-caustic applications to the endometrium, and trust that I may be pardoned for including under this caption pyosalpinx and hydrosalpinx.

The subject of aspiration and drainage by the vagina is not new, but it is a method which has been almost abandoned of late in favor of laparotomy and drainage through the abdomen. I believe, however, than I can present it in a more favorable light than has heretofore surrounded it. With our present perfected knowledge of antisepsis, there cannot possibly be the same objection to this outlet which formerly existed; besides, the addition to our resources of the antiseptic power of the galvanic current renders puncture and aspiration by the vagina harmless, when the condition is appropriate and the degree of penetration is limited. Apostoli says:

"I have found that the galvanic current sent through culture media of pathogenic microbes is *germicidal*, which confirms what I said long ago, that this current was *antiseptic*, and would *attenuate* or *sterilize* certain conditions of germ growth."

This, then, is one explanation of the success following vaginal punctures and aspiration by this method. I refer more particularly to the method of aspiration and drainage of fluctuating tumors by the vagina, as described in the *New York Medical Journal* of June 8, 1889. And I think that the general good results which I have obtained justify me in preferring and strongly advocating this method of treatment, in certain appropriate conditions, in lieu of other methods now in vogue.

Dr. H. R. Bigelow, in THE MEDICAL NEWS, May 18, 1889, writing from Paris, says:

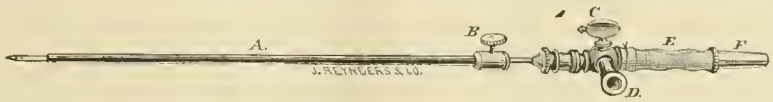
"In the French Academy of Medicine they are discussing methods of drainage by uterus and vagina, without the necessity of operating, so that the minds of the surgeons themselves are turned in conservative directions. I am sure that the time is in the near future when electricity shall solve the riddle."

As there may be some who have not read the article to which I refer, I will briefly describe the method and the trocar and canula which I use. It is a very fine silver canula, the size being No. 4 of the French scale, with a steel trocar, and covered with a slide of insulating material, which may be fixed by a screw to the shaft of the canula, so as to limit the degree of penetration. It is only capable of penetrating two centimetres, and it is seldom necessary to exceed one centimetre. The trocar is arranged for connecting with the battery, and the canula is made so as to be easily attached to an aspirator.

The method of application is simple; after deciding upon the degree of penetration necessary, the

[1] Read before the New York Academy of Medicine, Section in Obstetrics and Gynecology, November 27, 1889.

slide is fixed, and the trocar point is drawn within the canula. The vagina and vulva are douched thoroughly with a solution of bichloride, the index finger is introduced and, taking care to avoid any pulsating vessel, the most dependent point is selected. Then the canula, with the point of the trocar concealed, is passed along the finger until it impinges against the point selected, the trocar is pushed down into place, and the canula is made to penetrate to the limit fixed by the slide. The trocar



The cut shows a platinum canula and trocar (No. 4, French catheter scale) made for me by Mr. Reynders, for the galvano-tapping of pyosalpinx through the vagina. The shaft is covered with an adjustable sheath (*A*) of hard rubber for insulation. This may be fixed at any point by the screw *B* and the degree of penetration limited. At *C*, there is a three-way stopcock, and at *D*, a connection for an irrigator, as well as a socket for connecting with the battery. When the trocar *F* is withdrawn, an aspirator may be attached to the rubber tubing *E*, and, after the pus has been drawn off by a quarter turn of the stopcock *C* the cavity may be flushed with an antiseptic solution, passing in at *D* through the canula. By turning the stopcock straight again, the fluid is allowed to escape through the tubing *E* into the aspirator bottle. Care must be observed not to over-distend the Fallopian tube, the walls of which have been much weakened in some cases. That I may not be misunderstood, I repeat that I limit the degree of penetration usually to one centimetre, and deem the procedure appropriate only when the tube is close to the vaginal wall, full and tense, demanding immediate interference.

being then withdrawn, if no fluid escapes, the slide is readjusted lower down, and the canula, without the trocar, is introduced a little farther. When the fluid has been evacuated, the trocar is partially reintroduced and connected with the battery, the circuit being completed by a large clay electrode on the abdomen or back. In hydrosalpinx, the negative pole is used through the canula, with not more than 50 M. for five minutes; but in pyosalpinx, the cavity must be washed out with an antiseptic solution, as an extra precaution, and I prefer the positive pole because it is less irritating, and is believed to be more antiseptic, using 50 M. for five minutes. When the positive pole is applied, a canula made of platinum should be used, as the silver would be acted upon and unnecessary irritation provoked.

The cauterization of the track of the puncture by the current shuts it off from the surrounding tissues and renders the absorption of septic material through that channel impossible, and by using a safe intensity, not exceeding 30 to 50 M. for five minutes, nothing unpleasant is to be apprehended. (The higher intensities necessary for fibroids are not to be thought of in these conditions.) The opening remains pervious a short time for drainage, and closes readily when it ceases, and if a dressing of iodoform gauze is frequently renewed in the vagina, there is nothing to be apprehended from that source. Resolution in the diseased tube is promoted by the influence of the current and is subsequently still farther favored by mild positive galvanism of the endometrium, which will likewise be appropriate for the coexisting endometritis. I limit this treatment by aspiration to such tubes as are close to the vaginal wall, and where fluctuation may be distinctly felt. These tubes are usually fixed by a mass of exudation.

In these conditions, Apostoli adopts a somewhat different course. He punctures with his ordinary puncture needle, and allows the pus either then or subsequently to drain into the vagina through the puncture. But it appears to me that the method here suggested is better, because it at once gets rid of the accumulation which is a constant menace to the patient as long as it remains, and the cavity is rendered aseptic and put in the best possible condition for resolution. Dr. Bigelow says he has seen Apostoli puncture a pyosalpinx, enlarge the opening, and insert a drainage-tube with good result.

This treatment of hydrosalpinx was suggested to me by the radical cure of three cases of hydrocele by the same method. They had repeatedly refilled after ordinary tapping, but never refilled after using negative galvanism through the canula.

Small cysts close to the vaginal wall have been successfully treated in the same way. I have found one application usually sufficient in these small cysts, when the fluid is drawn off first and a current of 100 M. to 150 M., negative, is used through the canula.

The fibro-cyst is sometimes more obstinate in yielding to this treatment, especially those lined with a secreting membrane. Some I have found to yield to one tapping and negative galvanism of 100 M. through the canula; but in other cases it has been necessary to make the application directly to the cavity. This is done by enlarging the opening with gradually increasing sizes of conical electrodes connected with the negative pole, until it will admit a bulb-electrode into the cavity. This bulb is fixed upon a small insulated shaft which is flexible, and through it a current of 150 to 200 milliampères is concentrated within the sac. If drainage is not perfect through the opening, a rubber drainage-tube is inserted and fastened in position. A frequently renewed dressing of iodoform gauze is kept in the vagina.

I will cite one case here which will illustrate the success following this method of treatment:

The patient is married, and forty-one years old; one child at term, and one miscarriage. She has suffered for eight years at her menstrual periods with severe pain in the left side of the pelvis, radiating down the thigh, which often compels her to remain in bed for days at a time. Two years ago she was induced to visit the clinic of the Post-graduate School, where she saw Dr. Bache Emmet, who diagnosed a fibroid tumor the size of a quart bowl. She was placed under the care of Dr. A. P. Dudley, who offered to remove the ovaries. This she declined. She continued to suffer, growing worse all the time, the attacks of pain being more severe and their duration longer, so that never a month passed that she did not find it necessary to keep her bed for ten days to two weeks at a time, and, at the same time, keep under the influence of opiates. This was her condition in February last when she consulted me. I found the tumor to the left of the uterus, to which it was attached near the cervico-vaginal junction, and close to the vaginal wall. I also diagnosed a fibroid, and commenced treatment by galvanism. The intra-uterine applications were not well borne, so on February 26th, I made the first negative galvano-puncture through the vagina, using 250 M. for five minutes. This puncture was immediately followed by a discharge of an ounce and a half of yellow fluid, which caused me to suspect the cystic character of the tumor; but as it did not continue, and the tumor was very firm, I concluded that it was only a small cyst on the surface, which had been emptied.

March 5, the *second* negative galvano-puncture of 250 M. for five minutes was made. No discharge followed. Her menstruation appeared two days later, and there was much less pain than before.

March 12. Menstruation having ceased, the *third* galvano-puncture was made. This time the positive pole was used with 300 M. for five minutes.

April 10. The *fourth* galvano-puncture, negative, 200 M. for five minutes.

18th. The *fifth* galvano-puncture, negative, 200 M. for five minutes.

25th. The *sixth* galvano-puncture, negative, 200 M. for seven minutes.

A week after this puncture a copious watery discharge suddenly came from the vagina, and continued to flow away in gushes. Investigation showed that it had come from the last puncture-track. The opening was enlarged, and the sound could be passed up four inches into a cavity. All the fluid was drawn off, but the discharge continued for two weeks—as much as a pint a day.

May 18. A bulb electrode was introduced, and 150 M. negative galvanism applied to the cavity for eight minutes. Three days later all discharge ceased. She has had no pain since, and her menstruation has been normal. At the present time—six months since the last application—she is in perfect health. What remains of the tumor is about the size of a hen's egg. It gives her no inconvenience whatever. She has been seen recently by Dr. Dudley, who can vouch for her present condition.

The dermoid cyst may be treated in the same way as the fibroid cyst, when it contains only sebaceous matter, for the negative pole will soften it, and allow it to drain away. My experience is limited to one case in the pelvis, though I have succeeded in curing several on the surface of the body by this method. In this instance the tumor had been diagnosed as a small fibroma. At the first puncture a cavity was discovered, but there was no drainage from it. On enlarging the opening as before described, and exploring the sac, the nature of its contents was ascertained. Fifty milliampères negative galvanism were applied to the interior of the sac, a drainage-tube inserted, and a dressing of iodoform gauze placed in the vagina. This application was repeated every second day. Eight negative galvano-caustic applications were sufficient to empty the cyst completely. It soon ceased to discharge and healed up. Now, four months after, there is scarcely a trace of it to be felt.

I fully realize that such treatment could have no effect upon the bone, hair, and teeth often found in these cysts, but these might be removed through the opening if the tumor was situated close to the vaginal wall. In the case just mentioned the cyst contained only sebaceous matter.

The condition known as chronic pelvic cellulitis, which is usually manifested by a mass of exudation in one or both broad ligaments, including the tube and ovary, and associated with salpingitis and endometritis, yields very satisfactorily to galvanism of the endometrium. But it is very important to begin the treatment with a small dose—say 20 to 30 M.—for three to five minutes every second or third day, using the positive pole. And it is sometimes even better to begin with vaginal applications. The dose may be increased to 50 M. as tolerance is established. Later in the course of treatment it may become necessary to substitute the negative pole or vaginal puncture to hasten absorption. This condition dooms the patient to a life of misery, constantly threatened with peritonitis. Laparotomy does not always cure; but, by galvanism, she can be promptly relieved of pain, the deposit is softened and absorbed, the inflammatory complications are removed, and she is eventually restored to health with her ovaries and tubes intact and with a chance of conception. A case of this kind has recently come under my observation, and though it is only one of many others, some points in connection with it may be of interest here.

The patient had a miscarriage two years ago, and an attack of acute pelvic cellulitis in January last, from which she recovered partially, so as to be able to go about, but always suffered great pain in the right

side of the pelvis on standing, walking, or riding. Frequently the attacks of pain were so sharp as to send her to bed for several days, especially at the menstrual period. In the beginning of October she visited a clinic in this city, and was told that she had a tumor which was liable to burst and cause her death, and that it must be removed without delay. Careful examination, under chloroform, shortly after, when she consulted me, failed to reveal anything except a firm mass of exudation surrounding the right tube and ovary, and a retroflexed uterus partially fixed. The mass was extremely sensitive to touch, and the patient could scarcely walk a block. Treatment was begun with 30 M. positive galvanism, intra-uterine, three times a week, and the dose gradually increased to 60 M. She ceased to complain of pain after the sixth application. At this date she has had ten applications, and her improvement is marked. She can walk or ride any distance without pain or inconvenience, and is able to do her own work. The mass is less than half its original size, and not sensitive to ordinary pressure.

All of these cases, however, especially those of long standing, do not yield so readily to the intra-uterine applications alone, and it is then necessary to resort to vaginal galvano-puncture as advised by Apostoli. He uses a very fine needle, adjusted so as to penetrate only a half centimetre, using fifty milliampères, positive, for five minutes. I have seen marked benefit follow such punctures, both in my own cases and those which I saw treated at his clinic. The patients themselves remark the increased benefit following this form of treatment. It may be more painful at the time, but the result, they say, outweighs the pain of the application.

The intra-uterine chemical galvano-caustic applications exert a decided influence upon fibroid tumors attached to the uterus, but which are not accessible for vaginal puncture, especially if they can be treated by including the growth between the two poles for the interpolar action. Dr. J. H. Gunning, of this city, tells me that he has had remarkably good results from the interpolar action of the current alone.

It would seem unnecessary to add further testimony in favor of the treatment of uterine fibroids by electricity, since such authorities as Spencer Wells and Thomas Keith have abandoned hysterectomy and openly avow themselves in favor of Apostoli's method. But there are some who refuse to be convinced, and some who, having tried it improperly and failed, are unwilling to admit that any good can come of it.

As to fibroids,[1] it does not always dissipate the tumor entirely, but the size is very materially lessened; its growth is arrested, and the symptoms are relieved. The pain is promptly lessened, hemorrhage is absolutely controlled, and, as the tumor becomes reduced in size, the pressure symptoms are likewise removed.

It sometimes requires a great deal of patience on the part of the physician, as well as the patient, and strong confidence in the agent, to make both hold out to a successful end. Thomas Keith truly says:

"Apostoli's method, though slow, requiring much patience, tenderness of manipulation, and thought, is still sure in its results."

He also adds of electricity:

"My confidence in its power to relieve disturbing symptoms of uterine fibroids and to cure many chronic inflammatory conditions in the pelvis continues to increase, and I have no fears for the future of electricity. . . . Hysterectomy, remember, which is performed every day for a complaint that rarely of itself shortens life, kills every fourth or fifth woman who is subjected to it. This mortality must cease; it is not a question of surgery, it is a question of humanity. Every time that any disease can be cured without resorting to a bloody and dangerous operation, such as hysterectomy, progress is made in our art, and there is a gain to humanity, while surgery is the better of being purged of a deadly operation. Even the fact that in my cases of hysterectomy the removal of the uterus and ovaries was sooner or later followed by insanity in ten per cent. of the whole number, is enough for me to condemn any operation that removes these organs."

And this is the mature opinion of a most successful surgeon; one who was the first to lower the mortality of abdominal surgery.

The method of application should be more clearly explained and clinically taught in this country, for there are many to-day who have but a superficial knowledge of electricity, and some who are attempting to use this agent without even knowing the difference in the action of the galvanic and faradic currents, as well as many who do not realize the difference in the action of the two poles. This is a deplorable fact, but, nevertheless, true, as the following incident will attest:

A lady consulted me recently about a tumor which proved to be a fibroid growing from the right side of the uterus. She volunteered the information that she had no confidence in electricity, because her physician had been treating her for the past six months with that agent, and it had not only done her no good, but she was worse. He had told her that he did not himself think it was suitable for her case after he had given it a thorough trial. On inquiry, I learned that he did not possess a galvanic battery, but had treated her with a small faradic battery, even puncturing with that current. That man is prepared to denounce electricity as worthless. This patient has now been under my care since the middle of September, has had twelve positive galvano-caustic applications to the uterine canal, and one positive galvano-puncture. Previous to consulting me, she suffered constant pain, menstruated twice a month, and for

[1] Dr. Goelet stated that as others would discuss the subject of electricity in fibroids at the same meeting it would be unnecessary for him to enter into it in detail.

seven or eight days profusely. She has had no pain since the sixth application. Her last period, which was twenty-nine days after that of the previous month, lasted only three days. She is now progressing nicely, can walk or ride without pain or fatigue, and the tumor is smaller and very much softer.

After giving Apostoli's method, as I understood it, a thorough trial, I thought enough of it to visit him during the past summer and learn more about it. It is a mistake to suppose that any one can apply this method without special preparation or instruction. And I am now satisfied that Apostoli is but poorly understood by many who think they can grasp his ideas by reading his writings. It is necessary to see its practical application in order to comprehend it fully, and there is too much in the method to be learned in one or two visits to his clinic, even by those who understand electricity. A correct diagnosis is the first requisite, then experience alone will enable one to decide the course to be pursued, else the negative pole will be used when the positive is indicated, and *vice versa*. It is very necessary to understand the technique of the application and to have confidence to administer it properly, taking care that self-confidence does not overstep the bounds of prudence. Always respect the actual suffering of a patient, but do not be deceived by her nervous apprehensions. By knowing the condition, experience will tell you nearly how much of galvanism she can bear. Apostoli has pointed out that in fibroids there is a comparative insensibility of the endometrium to the current, and he also lays stress upon the fact of the increased sensitiveness of the endometrium in inflammatory conditions of the appendages. The fact being, that in all these last-named conditions there always coëxists an endometritis. But in uncomplicated endometritis the current is usually well borne. In treating diseases of the appendages, he says, begin always with the positive pole and a small dose and increase as tolerance is established. In fibroids, it is often possible to begin with 100 milliampères, and I have seen 200 used in the uterus without causing the patient manifest inconvenience. I have likewise seen galvano-puncture of 200 milliampères borne without much suffering when the pole used was positive. These and many other important points can only be appreciated by watching his work at his clinic.

I followed him closely while there, and came away more than ever convinced of the general utility of electricity in gynecology. One cannot but be impressed with the method of his work, his honesty of purpose, and conscientious painstaking toward his patients, as well as the courtesy extended the physicians visiting his clinic. He exhibits with the most perfect freedom the histories of his cases, the records of his treatment, and the results. Every case treated there may be examined and questioned by any one present, and, if you do not request it, you are invited to examine the patient and express your opinion. The notes of progress and the treatment are announced to all present, and recorded by his assistant, and one is at liberty to verify any statement that is made. Since I have seen for myself, I have been astonished at the statements made by others, which are so contrary to my own experience.

In conclusion, I desire to say that I do not think any one should condemn Dr. Apostoli or his method until they have visited his clinic and witnessed his work and his results.

243 WEST FIFTY-FOURTH ST., NEW YORK.

THE GALVANIC TREATMENT OF UTERINE FIBROMATA.[1]

BY E. L. H. McGINNIS, M.D.,
ELECTRO-THERAPEUTIST TO THE WOMAN'S HOSPITAL IN THE STATE OF NEW YORK; FELLOW OF THE NEW YORK OBSTETRICAL SOCIETY, OF THE PATHOLOGICAL SOCIETY OF NEW YORK, ETC.

I AM well aware that the above subject is one which has many times been written about, spoken about, and read about, and that there are few who have not already some idea of its utility; but there may be some who have formed opinions hurriedly or after insufficient trials, and as I welcome any additions to the literature on the subject, so have I ventured to hope that I could say something of interest to others.

It is needless for me to go into the history of this treatment of the uterine fibroid growth in detail, but as far back as 1871 Dr. Cutter had found the advantage of the continuous galvanic current, and since then many observers have been at work on it, and have from time to time published their memoirs on the subject.

There have been many different ways of applying the current to the tumor, all with the view of reducing its size and relieving the symptoms of this most unfortunate affliction; but I propose here to speak more especially upon a course of treatment which statistics and time have shown to be better in every respect than the others, viz., that first brought into prominence by its originator, Dr. Georges Apostoli, in an article read before the British Medical Association, in 1887.

He had then used it for five years, with most satisfactory results, and since that time he has steadily continued to study it in all its details, and reduce what had hitherto been a vague sort of empiricism to an exact science. This step in itself was all-important, for many had tried galvanism, with a large number of failures and only occasional suc-

[1] Read before the New York Academy of Medicine, Section in Obstetrics and Gynecology, November 27, 1889.

cesses, and of the latter no one seemed to know exactly why good had been done.

By the introduction of improved electrodes and a good milliampèremeter, however, we are now able to accomplish results entirely satisfactory to the vast majority of patients treated by it, and most gratifying to the attending gynecologist, and it is my firm belief that ere long its use will be universally recognized as the proper course to pursue before resorting to an operation the dangers of which we all know only too well.

Even to-day we come into contact with empiricism regarding the use of electricity, as it is practised by charlatans or those ignorant of its proper handling. I have been told by patients, of the faradic, interrupted galvanic, and static currents having been used on them for the cure of their fibroids, and one told me not long ago that a female practitioner, supposed to be largely endowed with "natural electricity" (whatever *that* may mean), had treated her tumor with electricity by rubbing nearly all the outer layer of epithelium from her abdomen, and with the temporary relief which massage sometimes brings. Is it to be wondered at, then, that there are sceptics regarding its use?

Since my appointment as Electro-therapeutist to the Woman's Hospital several years ago, I have had abundant opportunity to test the values of the different methods of application, and have found the results of those cases treated by Apostoli's methods to be far better than the others. Puncture through the abdominal wall seemed to produce fair results in some cases, but I do not consider it as efficacious as Dr. Apostoli's method. Although the *modus operandi* of it is comparatively well known, a hurried description may elucidate much that follows.

He introduces one electrode, shaped like an ordinary uterine sound, into the canal, and the other, a moist pad of potter's clay, is placed upon the abdomen over a prominent nodule, if there be one, or at the upper limit of the growth, if it be rotund. These are then connected with the battery by the flexible conducting cords, one of which must reach the battery by way of the milliampèremeter, as the amount of current used is to be accurately measured. The current is then turned on, its strength increased very slowly and without shock, till the proper number of milliamperes is reached, and is kept there from five to twenty-five minutes, depending upon the susceptibility of the patient, etc., and is then reduced in the same way, great care being taken to avoid any sudden break in the current, which would cause a shock to the patient. This method will answer for most cases in which the mass is situated in, or attached to, the fundus or anterior wall; should the situation or attachment be the posterior wall, galvano-puncture is resorted to, with a trocar-pointed electrode. Its application is as follows: A careful vaginal examination is made, and the posterior cul-de-sac thoroughly explored, any pulsating point being located, and avoided thereafter. When a spot free from pulsation is found, the end of a small celluloid tube is placed against it and the trocar-electrode, with the handle firmly screwed to the end toward the operator, is passed through the celluloid sheath and the puncture made to a depth not exceeding one to two centimetres. This celluloid tube answers a double purpose: that of insulating the needle from the vagina and of preventing the point from entering too far or beyond the distance intended and previously arranged for. Should much hæmorrhage occur when the needle is withdrawn, an accident I have never known to happen, a bivalve speculum can be introduced and forceps applied, or the positive pole be made to act as a hæmostatic.

This treatment is often administered without an anæsthetic, and the strength of the current should be no more than the patient can tolerate. It should also be remembered that the current itself, in two or three moments, has a distinct local anæsthetic effect, thereby lessening the pain and allowing an increase of quantity. A current of 30 milliampères has been found to produce benefit, and up to a certain point, stronger ones in proportion. I find that from 75 to 150 milliampères can be quite comfortably borne, and certainly produces most marked improvement.

While trying to get exact measurements of the tumor in every case, it is often extremely difficult to do so, owing to the presence of gas in the intestine behind the mass, to the thickness of the abdominal walls, etc. One thing that I have noticed is misleading, viz., that in some cases which have been treated by this method, as the tumor diminishes in size an increased amount of adipose tissue is found in the abdominal wall. This point should not be overlooked when external measurements are taken for comparison with former ones.

The *proper* use of the poles is of the greatest importance. To make a definite rule as to which should be used internally is impossible, as the nature of the symptoms will be our guide. In the class of non-bleeding fibroids, the *negative* pole is indicated for two reasons: first, because it seems to curtail the supplementary circulation by means of the rapid atrophy it causes, especially where puncture is made, and, second, because Dr. Apostoli has found that in bringing about a reduction of the mass, it is quicker. For the treatment of bleeding fibroids, the hæmostatic action of the positive pole has been too well proven to require extended notice. Not one single case of this kind which I have treated by the Apostoli method has failed to give the greatest satisfaction to both patient and myself. Cases have come to

me nearly exsanguinated, and I have managed by this means not only to stop the hemorrhage, but, to my delight, prevent its return. Surely, had the treatment no other merits, this one in itself would entitle it to a fair trial before operative procedure is resorted to.

It is not my intention to claim any more than can be proved by many who are using it to-day, nor that a few applications of it will cure any and every fibroid with which it is possible for one to meet. That it is slow in its effects I know, and we must not be disappointed if marked diminution in the size of the mass is not noticed at once. The great majority of cases show little change under a month of treatment, which should be applied three times weekly. But I have found one (very rarely, two) thorough applications quite sufficient to control the most obstinate hemorrhage, provided a sufficiently strong current is used, and, what is *most* important, that every part of the endometrium be brought in contact with the electrode. This is sometimes very difficult, as the canal may be tortuous, and the stiff electrode then fails to touch some spot where there is bleeding. This may be provided for by the use of a flexible electrode, which is insulated to its platinum tip, which latter should be three-fourths of an inch long and shaped like a probe, but of larger calibre. Having passed it to the entire depth of the uterus, it is held there, with one finger against the os, long enough to cauterize the parts in contact with the tip (the time to depend upon the strength of the current used), then gradually withdrawn, a very little at a time, till the entire endometrium has been cauterized. Should there be fungoid growths present, causing some if not all of the hæmorrhage, they will be destroyed at the same time, thus answering the purpose of curetting, and without leaving a fresh bleeding surface within the uterus.

All these measures should be carried out in a rigidly antiseptic manner, washing out the vagina with a bichloride or carbolic solution, before and after each application, and immersing the intra-uterine electrode in a saturated solution of iodoform in ether, just before introducing it. The ether instantly evaporates, leaving a thin deposit of iodoform on the electrode. Should germs even then be present, the current will be more than sufficient to destroy all life in them.

No new method of treatment is brought before the profession without its detractors. This I consider most fortunate, as it leads to discussions and narrations of cases which cannot fail to instruct us, and many interesting features are thus developed, which are of the utmost value.

One of the objections raised to the employment of the Apostoli method is the danger of a current strong enough to produce beneficial results. *Improperly* used, I grant that damage may be done; but does a badly managed case of hysterectomy always get well? I would ask those who have made this objection to compare the results of the laparotomists with those who have treated an equal number of cases by this method; the latter will be found much less dangerous to the lives of the patients, to say nothing of the long convalescence, pain, possible mania, inability to continue in daily avocations, and hæmorrhage during or after the operation. The experience of such well-known gynecologists and authorities as the Keiths, father and son, Sir Spencer Wells, Woodham Webb, Playfair, and others in Great Britain alone, must certainly silence many objections regarding its inutility, while in this country, men of undoubted ability have met with results far beyond their expectations. Often the patients themselves can judge of their improvement quite as well as the attending gynecologist, for who knows better than they that the pain and sense of pressure, the dreaded hæmorrhage, the headache and backache so constant, as well as other reflex symptoms, are not what they once were? Who can tell better of the apparent loosening of the waistbands attached to their clothing?

I have now under my care a case sent me by Dr. T. Gaillard Thomas, through whose courtesy I am enabled to report it:

The patient was first seen by me in February of this year, and her history revealed the fact that she had noticed the enlargement in her abdomen four years ago; she had all the usual symptoms, including several most severe hæmorrhages, each of which had left her nearly bloodless. She was emaciated to an alarming extent, her pulse was weak, and she felt perfectly certain that the next hæmorrhage would be her last, and that she could not recover from the effects of a hysterectomy. Her tumor was situated in the fundus, and extended to the ensiform cartilage; her waist measured forty-four inches in circumference, and examination revealed that her uterus was five and one-half inches deep. Fortunately the canal was straight, so I had little difficulty in introducing the electrode, and thoroughly cauterizing the endometrium. I began treatment at once, and continued it with two intermissions of two weeks each, when she was obliged to leave town, and also during her menstrual periods, till my departure for Europe, the last of June, and did not see her again till on my return, October 1st. She has had no renewal of hæmorrhage: her tumor is now down to the umbilicus; is not tender, and gives her no pain; the canal is three and one-fourth inches long, and she can walk to my office, nine blocks from her home, three times weekly for her treatment, and can undergo the fatigue of a day's shopping with only a moderate amount of discomfort.

I could occupy the reader's attention with the narration of other cases were it advisable; but I

feel that I cannot close this paper, already too long, without reference to an article written by Dr. Thomas Keith, of London, and published in the *British Medical Journal* of June 8, 1889. In it he says:

"What I now plead for is, that for a time all bloody operations for the treatment of uterine fibroids should cease, and that Dr. Apostoli's treatment, *as practised by him* [the italics are mine], should have a fair trial. Those who have hitherto most resisted the introduction of electricity are the surgeons who are best competent to carry it out. They are accustomed to manipulate in the pelvis, and they will not make mistakes of diagnosis, or make them as seldom as it is possible to do. Hysterectomy, remember, which is performed every day for a complaint that rarely of itself shortens life, kills every fourth or fifth woman who is subjected to it. This mortality must cease; it is not a question of surgery, it is a question of humanity. Every time that any disease can be cured without resorting to a bloody and dangerous operation, such as hysterectomy, progress is made in our art, and there is a gain to humanity, while surgery is the better for being purged of a deadly operation." . . .

"It may seem strange to some, that after the results I got in hysterectomy—results which almost make it justifiable—I should now begin to throw stones at the operation, instead of trying still further to improve upon it; and but for Dr. Apostoli, I should now be doing so. I would give something to have back again those sixty-four women that I did hysterectomy for, that I might have a trial of Dr. Apostoli's method upon them; and I would give something never to have had the tear and wear of flesh and spirit that these operations cost me, for in scarcely one of them was the operation simple.

"I have, in the meantime, said my say, and it must not be forgotten that the opinion here expressed as to the value of Dr. Apostoli's treatment is not that of an unsuccessful surgeon, but is the deliberate opinion of one who was the first to lower to a minimum the mortality that so long followed abdominal surgery, and who, by the best results yet obtained in hysterectomy—results that Dr. Playfair is pleased to call almost phenomenal—still retains that position."

What can I add after such an opinion as the foregoing? I can simply say that my experience with Dr. Apostoli's methods, while large, is more than satisfactory, and in quoting Dr. Keith's praise and thorough indorsement of it I have expressed my own views.

While abroad on business last summer, I was enabled to visit Dr. Apostoli's clinic and to satisfy myself on many points regarding his histories and statistics, and I earnestly advise all who can possibly make an opportunity, to see him at his work in the Rue du Jour, to do so.

You will be welcomed by a most charming and courteous gentleman, who will give you every possible opportunity not only to see him operate, but to examine his cases and their histories, talk with them, ask them any questions regarding their condition and treatment that you may see fit, and, in fact, satisfy yourself on every possible point of the truth of his assertions and the merits of his methods. You will also meet colleagues from Germany, Russia, Scandinavia, and the South of Europe, as well as many English surgeons of renown, a few South Americans, and, I am proud to say, a goodly number of our own countrymen; and nearly all have the same opinion as to the merits of Dr. Apostoli's treatment, and seek his clinic for further instruction.

In conclusion, let me urge upon the reader to give this method a *proper* and *thorough* trial before rushing his afflicted patient to the operating-room, there to undergo the dangers of the knife.

35 WEST THIRTY-EIGHTH ST.

NOTES ON THE TREATMENT OF FIBRO-MYOMATA BY ELECTRICITY.[1]

BY A. H. BUCKMASTER, M.D.,
ASSISTANT SURGEON TO ST. PETER'S HOSPITAL, BROOKLYN, N. Y.

THIS method of treatment has been before the profession for several years, and, while the consensus of opinion is decidedly in its favor, there are many who are disposed to deny its efficacy. The treatment requires patience, it is slow, and in cases where the tumor is treated solely on account of its size it is often impossible to gauge accurately slight variations. Constipation, flatulence, increase in adipose tissue, congestion or œdema, all are apt to mislead and perplex the observer. There are several means by which the sceptical may become convinced that the treatment is valuable.

First. By statements of individual observers, many of whom have not only claimed relief from symptoms and decrease in size, but also total disappearance of myomatous masses. The evidence of this class is most abundant.

Second. The testimony of individuals supported by the observations of disinterested witnesses. This can best be obtained in the hospitals, and a competent man should be invited to test the cases, who should be a thoroughly practical gynecologist as well as an electrician, and competent to recognize the contra-indications for treatment.

Third. The presentation of a reasonable explanation of the means by which the results are obtained. The explanation of the writer is founded on experiments on the non-striated muscular tissue of the dog's heart and on fibroid tissue outside of the body. The experiments were as follows:

The heart of an anæsthetized dog was exposed and a current of forty milliamperes made to traverse a portion of the ventricle. A piece of the ventricle in the direct line of the current was excised and another some little distance from the direct influence of the current. When examined under the microscope the piece from the direct line of the current showed that the striæ had become markedly granular, while the piece outside of the direct line of cur-

[1] Read before the New York Academy of Medicine, Section in Obstetrics and Gynecology, November 27, 1889.

rent preserved the muscle cells unaltered. This granular appearance of the striæ would indicate degeneration of the muscle bundles. It is observed in fatty degeneration, and in such cases the contractility is much impaired. This is the first evidence of absolute molecular disintegration of living cells by the interpolar action of the galvanic current, where such process is confined to the cells.

The condition of rigor mortis is readily induced in a muscle through which circulation is maintained. The action of heat at 118° F., distilled water, acids even of the weaker kind, such as carbonic acid, bring it about. If death rigor occurred in any considerable part of the muscle tubes of the tumor there would result a marked diminution of its irritability, for it is a well-known fact that muscle under this condition ceases to respond to stimuli. To determine if this was so after treatment the following experiment was resorted to:

It is assumed that the contractions of the uterus are followed by contractions of the vagina which are in direct proportion to them. Kehrer[1] found in his experiments with rabbits, that exposure to air would give rise to a contraction which advanced through the whole genital canal, while by chemical, mechanical, electric, and thermal irritation contractions could be started at almost any point and were transmitted in one or the other direction, so that an increase in the vaginal pressure would indicate a contracted condition of the uterus. This method of indicating contractions of the uterus has been utilized by Milne Murray,[2] of Edinburgh, in his experiments on the effects of hot water on the uterus. The following method was adopted by the writer: A rubber bag by which the vaginal pressure is to be determined is filled with water and communicates by a rubber tube with the proximal arm of a U-shaped glass tube which contains mercury. The other arm of the glass tube is opened at the end. When any pressure is made on the bag the column is pushed back, and this raises the discus of the mercury in the distal arm. The variation can be read by means of a graduated scale. The chief sources of error in using this means of measurement arise from having air mixed with the water, or having the tube of such thin rubber that it readily becomes distended by pressure.

There are two methods of measuring the effects of stimuli on muscular contraction; one is by observing the comparative strength of the contraction, and the other is by ascertaining the smallest amount of current that will give a contraction; the latter method was in this instance adopted. The induced current with a sliding induction coil was used. The cell used was a constant one. The patient in position, the electrode was placed in the uterine canal. The bag filled with water was then introduced, and after waiting five or six minutes for the vagina to become accustomed to it, the faradic current was very gently turned on (the other arrangements being exactly similar to those used in the ordinary treatment) until contractions were induced in the uterus. The amount of this current was carefully calculated. The constant current was now gradually substituted by means of a rheostat until sixty milliampères were registered. In about a minute the column of mercury showed an increased vaginal pressure of one-sixteenth of a pound.

The current was turned off very gradually, and the patient allowed to remain perfectly quiet for twenty minutes; at the end of this time the slightest induced current that would give a contraction was considerably less than before the treatment [1]

The above experiments only point out a line of investigation. The writer has not had the time to repeat and test them as should be done; he merely indicates from the standpoint of the clinician what the laboratory worker may establish or disprove. So much for the interpolar action. In regard to the action at the poles it must not be forgotten that slight traumatism of the cavity of the uterus has an important effect upon the nutrition of the fibroid, and that there are many cases where fibroids have spontaneously disappeared. Gusserow states that various operative procedures, sponge-tents, incision of the mouth of the uterus, and intra-uterine injections frequently cause sloughing of fibro-myomata by interference with nutrition from traumatism of the uterine mucous membrane.

It is not my intention to narrate the histories of my cases, which present nothing brilliant in the way of cure. In no case has there been lack of improvement, in no case have I seen disappearance of the fibroid.

In regard to the technique of the operation there has been but little improvement of late. The literature of the subject is, and has been, overburdened with descriptions of visits to Apostoli and of his methods. A thorough knowledge of French is necessary to form any adequate personal opinion of Dr. Apostoli's work, or to comprehend the statements of patients, and this requisite must present an insurmountable difficulty to many of these witnesses.

To Dr. Austin Goelet, of this city, is due a cheap and efficient electrode with which many electricians are familiar. One fact has, I believe, escaped attention in stating the dangers incident to these cases, and that is, chronic renal disease. Not only should the urine *in all cases* be examined for albumin, but

[2] Edinburgh Med. Journal, Aug. and Sept. 1886.

[1] Unfortunately the writer has been unable to repeat this experiment, but hopes that others may do so.

the amount and specific gravity should be carefully considered. The writer has seen this complication assume most serious importance, and it should never be overlooked. In closing these brief remarks I desire to say that I believe that dissatisfaction in the treatment is usually due to failure in understanding and carrying out the principles enunciated by Apostoli.

207 CLINTON STREET, BROOKLYN.

BI-POLAR FARADIZATION IN GYNECOLOGY.[1]

BY A. LAPTHORN SMITH, B.A., M.D., M.R.C.S. ENG., F.O.S. LOND.,
SURGEON TO THE WOMEN'S HOSPITAL AND LECTURER ON GYNECOLOGY IN THE MEDICAL FACULTY OF BISHOP'S UNIVERSITY, MONTREAL.

ELECTRICITY is such a new subject and its different departments are so numerous that it is no easy matter for all of us to keep pace with its progress.

As is generally known, it was Faraday who discovered that an induced current of electricity is set up in a conducting wire which is placed near to, but not touching, another wire through which a current is passing. It is also well known that the appreciable effects of the passage of a current of electricity, either direct or induced, are greatly increased by the interruption of the current. Thus a continuous current of a hundred milliampères can easily be borne, while if the same current be interrupted it will promptly knock one down. By making the primary wire into the form of a coil and placing a piece of soft iron within the coil the iron becomes magnetic whenever the current passes, and this body of magnetized metal in turn intensifies the current in the primary coil. The primary coil should be made of moderately coarse wire so as not to offer too great a resistance for the battery to overcome, as the battery, which should consist of two closed cells in a separate portable case, must have sufficient electro-motive force to push through the coil. The secondary or induced coil deserves special attention because it will depend entirely upon the shortness and coarseness, or the length and fineness of the wire, whether you will obtain those almost magical effects which some have claimed for it. There are many who cannot believe that these differences are of any real consequence, and yet there is no fact in medicine of which I am more certain than that the results from these two wires are totally different. The coils which I have been using for the past three years are wound as follows: the short wire coil, which is about twenty-five yards long, and No. 14 or 16 in diameter, is insulated with silk and varnished between the layers. The fine wire is about No. 40, which is the finest made, and is about a mile long. The short, thick wire gives out nearly the whole quantity of current that is induced in it, and is, therefore, called the current of quantity, while the long, fine wire offers a tremendous friction or resistance to the passage of the current, and is, therefore, called the current of tension. I think this is a better name for it than current of *quality*, which it has sometimes been called. The current of quantity from the coarse coil, as has long been known, is an excellent tonic for muscular fibre, and I have used it to advantage in nearly every case in which the symptoms could be traced to defective muscular contraction. It should be placed high in the list of tonic remedies, although I do not think that it possesses any miraculous virtues which are not possessed to a greater or less extent by gymnastics, regular exercise, strychnine, quinine, ergot, hydrastine, and cold and hot water. This much can be said for it, however, that it is a tonic especially suitable for relaxation of those muscles which, owing to adverse circumstances, cannot be toned up by any or all of the above mentioned means, and, besides, it can be made directly on the muscles or group of muscles which are most at fault. By means of Apostoli's bi-polar electrode it is especially applicable to the muscular organs in the pelvis. For instance, in post-partum hæmorrhage we can surely obtain instant and permanent contraction of the uterus, no matter how exhausted it may be, by introducing the bi-polar electrode and turning on the coarse wire current.

For those obstetricians who are frequently meeting with this accident, a small battery which can be set in action in an instant, might well find a place in the modern obstetric bag. I must confess, however, that I have never put it to this use, for, although I have been looking for a case on which to try it, since I have been giving nature a little more chance I find that relaxation of the uterus is more and more rare. I have had, however, many cases of subinvolution due to the defective contraction of the uterus, accompanied by the usual symptoms, and they have invariably been promptly relieved, and in a very reasonable time cured, by *séances* with the bi-polar intra-uterine electrode with the current of quantity as strong as the woman could bear it, and lasting ten or fifteen minutes. But it must be remembered that no such gratifying results will be obtained if the enlargement is due to fibrous tissue instead of muscle. Areolar hyperplasia, like fibroid, must be treated by the continuous current. Another class of cases with which I have had very gratifying results are those of deformity and displacement of the uterus, due to relaxation of its walls or of the muscles which hold it in the centre of the pelvis. The presence of strong adhesions, however, binding it down in a wrong shape

[1] Read before the New York Academy of Medicine, Section in Obstetrics and Gynecology, November 27 1889.

or position, would diminish the probability, or even preclude the possibility of restoring it to its proper form or position. The cases in which I have been occasionally disappointed, were those in which the muscles of the uterine supports had undergone degeneration so long ago that there seemed to be little or no muscle left to work upon. In such cases I have abandoned this treatment for some more speedy one.

This treatment is not at all applicable to cases of bleeding due to fungous endometritis, or to the presence of retained placental tufts. In those cases it is our manifest duty to remove them with the curette or, in the case of fungosities, to destroy them with the continuous current. The coarse wire faradism, however, is comparatively well known, so I need say no more about it. The advantages of the bi-polar method are:

First. It is less painful than the old method because it does not require the current to pass through the skin, which is much more sensitive than the vagina.

Second. It is easier to apply because it dispenses with the need of an assistant.

Third. It allows a much stronger current to be tolerated.

Fourth. It is consequently more effective because the higher the intensity of the dose the more marked the effects.

These bi-polar electrodes are made with one pole at the extremity and the other separated from it by an interval of an inch or so of insulating material, so that the current has to go through the tissues to get from one pole to the other. In doing so, it seems to set up circles of induction in the neighboring structures, as proved by the following observation: when the current is started with a moderate strength from the fine wire coil the patient, if asked what she feels, will say that there is a numbness of about the size of a walnut. As you slide the secondary wire over the primary more and more, she will say that the area of numbness has increased to the size of an orange, and finally when the whole strength is on, the numbness will have invaded the whole pelvis, including the area of pain. This can only be accounted for, I think, by the fact that induced currents are set up in the successive layers of tissue, which in a way take the place of contiguous wires on the telegraph poles. These bi-polar applicators are made of several sizes; two or three for the uterus, varying from the diameter of the uterine probe to that of the ordinary sound; and as in certain cases, such as pregnancy, it may not be desirable to introduce anything into the uterus, there are several sizes made for the vagina. But one uterine and one vaginal electrode are practically all that are required. As a rule, the preference should be given to the intra-uterine applications because they are much more effective than the vaginal ones.

We now turn to a short description of the qualities, indications, and methods of application of the comparatively new, and in its effects almost magical, current from the fine wire. I have already said that it causes very little muscular contraction, but that it has the power of affecting the nervous system. The element of pain plays an important part in the diseases of women and very often exists where no organic lesion can be found. More especially is this the case with ovarian pain, a great many cases of which I have completely cured with less than a dozen applications of the fine wire faradism. How it does this I am unable to say. Apostoli thinks that it sets up vibrations in the nerves, travelling in an opposite direction to the ordinary or painful impulses. Perhaps the current of tension filling the nerve-fibres dams back the painful impulses, or perhaps the vibrations are so rapid that the conducting power of the nerves is temporarily lost; but I think that Apostoli's explanation is the best.

There are three kinds of cases in which I have found the fine wire bi-polar faradization remarkably beneficial. They are:

First. Ovarian pain where no organic disease could be found. I do not pretend for a moment that it would be of any use in even small ovarian cysts—the sooner they are removed by operation the better. When I see these on our society table I feel no regret that they have been removed; but when surgeons remove healthy ovaries on account of pain only, I feel sorry that they were not aware how easily that pain could have been relieved by fine wire faradism. The first sitting should last ten, twenty or even thirty minutes, if it is that long before the patient can say that her pain has gone; it is then well to tell her that she may expect the pain to return after a few hours, but that each day it will stay away longer and longer, until after a variable number of sittings, rarely more than ten, the pain will remain away altogether.

Second. In cases of abdominal pain due to hysteria it acts promptly, not only in rendering the abdomen insensitive to pressure but also in calming the general nervous crisis within a few minutes. This was one of the observations which struck me most at Apostoli's clinic, that women who could scarcely bear to be touched with a feather on the abdomen, could, after five or ten minutes of fine wire faradism in the uterus or even in the vagina, endure any amount of kneading and punching without the slightest discomfort. In fact, parts which before were hyperæsthetic had now become anæsthetic. This has caused the charge against Apostoli of curing such cases by means of hypnotism, but I feel sure that this is not the case, be-

cause he does not possess that strange power, and besides many of the patients were totally ignorant of the nature of the treatment and its effects. This tolerance of hysterical patients for the full strength of the current of tension has often made me think that my apparatus was not working, until I attempted to test it on my own hand, when I found it unendurable with one-fourth of the intensity which the patient could easily bear. On trying the same strength on well women you will also find that they cannot stand a quarter of the dose that an hysterical woman can.

As I have already said, the current must be increased gradually in all cases, but *very* gradually when the pain is of an inflammatory nature. In bringing an application to an end, it is necessary to turn the current off before withdrawing the electrode, for the simple reason that the passage of the current over the much more sensitive vulva would cause the patient to shriek, although she could bear the same amount of current in the uterus or vagina without feeling it.

Third. There are many women about the age of thirty who, though fleshy and apparently well supplied with blood, do not menstruate at all, or but slightly. These women feel uncomfortable; their *embonpoint* makes them weak and they have many nervous symptoms which place them in the category of hypochondriacs. Anything that will bring on a full return of the menstrual flow gives them immense relief. I know of nothing that will attain this object more surely than three applications a week of the current of tension to the inside of the uterus, between the periods. Not only will the flow be reestablished, but the uterus, which before measured less than normal, will soon develop to its full size. I am aware that there are other means of doing the same thing, but none of them is so satisfactory as this.

Fourth. In vaginismus I have found it remarkably effective. The condition is due to hyperæsthesia of the nerve terminals about the entrance of the vagina, and is really a form of hysteria. In most cases the other symptoms of hysteria, as abdominal tenderness, etc., are present. In such a case the treatment may begin with one or two vaginal applications, after which it will be easy to introduce the finger and to use the intra-uterine electrode. In some cases the hyperæsthesia may be concentrated upon or limited to a small area as large as a ten-cent piece. The removal of the over-sensitive nerves has been recommended by Hilton for this often very intractable condition. Apostoli has devised an electrode for such cases in which the two poles terminate in two hemispheres of carbon placed side by side and separated by a thin layer of gutta percha. When this is placed on the hyperæsthetic spot the fine wire current is forced to pass through the tissues in order to get from one pole to the other. With this instrument the current can be localized on two or three over-sensitive papillæ. In the worst case of vaginismus I have had in twelve years the patient was cured by three applications and became pregnant at the next ovulation.

Besides these four indications Apostoli has advocated a fifth, with which I have had no experience, viz.: in pelvic pain due to inflammatory conditions of the uterus or its appendages. I have feared so to use it because of its well-known stimulating effects, although it is true that iodine acts in the same way in similar conditions. Those who wish to try it will do well to remember Apostoli's warning not to push the strength of the application beyond the point which can be easily borne, while, on the other hand, in pelvic pain of non-inflammatory or hysterical nature it is sometimes an advantage to push the current rapidly until its full strength is turned on.

There are also some troublesome conditions of the bladder in which I have used bi-polar faradism with advantage, but which I have not the space to describe.

Before closing, I wish to disclaim any intention of considering bi-polar faradism as the only remedy in gynecology. Many of the conditions which we are called upon to treat are the natural outcome of wilful or ignorant disobedience of the laws of health, and bi-polar faradism will not allow women to break them with impunity. Neither should we forget that the genital organs are not the only organs woman has, so that while we are calming her pain with electricity we should at the same time be removing the unhealthy conditions of the body generally, on which often the local disorder depends. All that I do claim for it is that it is a valuable addition to our therapeutic resources, especially in those diseases of women in which other methods of treatment often fail.

REMARKS ON ELECTRICITY IN GYNECOLOGY AND A NEW PORTABLE GALVANIC BATTERY.[1]

BY FRANKLIN H. MARTIN, M.D.,
OF CHICAGO.

APOSTOLI'S method, which was promulgated less than three years ago, first astonished, then excited the admiration of the entire medical world. Astonishment was expressed at a method which recommended such extraordinary means, and which claimed such brilliant results. Admiration was excited by the brilliancy of the author's conception and the thoroughly scientific grounds upon which it was based.

[1] Read before the New York Academy of Medicine, Section in Obstetrics and Gynecology, November 27, 1889.

The instruments of precision introduced and made necessary by Apostoli's method have enabled us not only to prove or verify the value of his work and to substantiate his startling assertions, but to go on applying the sound principles he has evolved to the relief of many pathological conditions peculiar to the female pelvis.

One of the most important points to settle after the introduction of the high dosage system of treatment was the question of generation of current. We were aware that the ordinary batteries in use would give a maximum current strength through the body, from hand to hand, of but from eight to ten milliampères. Certainly, then (forgetting in practice what we only know in theory), we could not expect to get 300 milliampères with the same instruments. We soon found, however, from practical experience, that we were mistaken and that the battery which gave a current of but eight or ten milliampères through the enormous resistance of the body from hand to hand, would give a marvellously strong one through the comparatively small resistance offered by the abdominal walls and pelvic tissue, with properly constructed electrodes. We now know that the resistance offered by these parts with the clay, or some form of substitute for the clay electrode, is less than 200 ohms instead of 2000, as was originally supposed.

Any battery may be used which will give a maximum electro-motive force of fifty volts, with but small internal resistance, which is without vibration, undulation, or interruption, which can be perfectly controlled by the operator, and which can be gradually increased from zero to its maximum strength, and the reverse, without interruption. This includes the ordinary open circuit battery cells employed for office purposes, ranging in number from thirty-six to fifty—according to their electro-motive force. The Leclanché, the Law, and the Diamond Carbon are usually preferred. For all work, except when puncture is required with small exposure of needle surface (thereby increasing the resistance) or when extraordinary strength of current is required, the ordinary twenty-four to thirty cell zinc and carbon chromate of potash batteries, such as are manufactured by the Galvano-Faradic Battery Co., the Flemming, or the McIntosh Battery Co., are sufficient. My battery is the outcome of a series of experiments made with the end in view of bringing forth a small portable battery which would possess none of the objectionable features of the ordinary form and which would do the same amount of work as that required of the office stationary battery.

The cell is a form of the chloride of silver cell, of sufficient power to give an electro-motive force of one volt, and an ampèrage of $\frac{8}{10}$ ampère. So that a battery of fifty cells will do the same amount of work as thirty-six to forty Leclanché cells. A battery of thirty-five of these cells has done all of my outside work for a period of eight months, without change or renewal, and possesses greater working power to-day, because of decrease of its own internal resistance, than when I began. From experiments made with the battery it is estimated that it will run with ordinary use without recharging or without perceptible deterioration in strength from one and a half to two years. As the battery is free from action when not working, it will remain in active condition a length of time in direct proportion to the amount of work required of it. There are two sizes of this battery manufactured by the McIntosh Battery Co., of Chicago, one of thirty-five cells and one of fifty cells. The fifty cell battery will generate a current of 300 milliampères with the Apostoli electrodes or any of the approved modifications.

Next to the treatment of fibroid tumors of the uterus by galvanism, I have found the greatest satisfaction in treating inflammatory exudation in the pelvis. This includes all cases, from the simple thickening of one or both broad ligaments to complete fixation of all the organs of the pelvis, with a thick unyielding exudate matting everything together. All acute inflammation, except secondary points arising from the irritation of already hardened exudate, should have disappeared in these cases before treatment is instituted.

I speak advisedly, after a long experience with a large number of such cases, when I say that I do not believe that there is a case of the kind described which, if submitted to a persistent course of applications of strong doses of galvanism in the proper manner, cannot be cured. The exudate will gradually but perceptibly disappear, the pain from pressure upon nerve fibres and nerve points will rapidly diminish, sympathetic disturbances will be relieved, displacements caused by contracting bands will gradually give way, and the general mobility of the pelvic organs will return, while coincidently the general health is restored from the effect of the electricity on the general system.

The best results are obtained in these cases from comparatively strong doses of from 75 to 125 milliampères. The object must be, in applying the electrodes, to include between them, as far as possible, the area of greatest disease. This, occasionally, will admit the use of an intra-uterine electrode as the internal point of departure. When an intra-uterine electrode is employed, one of as large surface as practicable should be selected, to avoid undue concentration and cauterization, which would give rise to subsequent cicatricial contraction. In the majority of these cases, however, an intra-uterine electrode is not admissible because of the position of

the exudate. In such cases it is necessary to employ a vaginal electrode so constructed that a thorough diffusion of the current is obtained, in order not to cauterize the mucous membrane of the vagina. For that purpose I employ an electrode composed of a slightly curved, insulated staff terminating in an exposed metal ball which is thickly covered with absorbent cotton moistened with water. By this simple instrument I can select any particular portion of the vagina required, with a soft yielding contact surface and thorough diffusion. The cotton is applied to the instrument by folding a thick piece over the metal bulb, and fastening it around the staff at its point of attachment with the metal by means of a small rubber band.

This instrument can be inserted with or without a speculum—more easily without, with the patient upon her back and the hips drawn near the edge of the bed or table. If a speculum is used, it should, of course, be withdrawn before the treatment is commenced. When the internal electrode is in place, it should be attached to the negative pole of the battery. Having previously adjusted the external abdominal electrode and attached it to the positive pole, the current should be gradually turned on, employing every precaution to prevent the slightest break or shock, until a strength of from 75 to 125 milliampères has been reached, the maximum strength tolerated varying between these figures with the varying sensibility of patients. The sitting should last from five to eight minutes, when the current should be gradually reduced to zero and the instrument removed. The treatment should be given every second day. The staff of the electrode is easily unloaded of its cotton by means of the dressing forceps, thus making it possible to observe perfect cleanliness. Cleansing the staff thoroughly, and the use of a fresh covering and fastening each time, of course, being imperative.

This treatment persistently carried out will accomplish exactly what I claim for it. It will not only absorb the slight exudations which merely produce thickening of the vaginal vault, but it will cause the rapid disappearance of large, well-defined masses situated in the broad ligaments or in Douglas's cul-de-sac. It will cause ovaries, large and tender from the irritation of inflammatory products, to assume their normal condition by removing the cause of the trouble. It will cause the disappearance of strong bands of adhesion, no matter where situated.

It has long been known that *mild* currents, persisted in for a long time, would slowly cause disappearance of superficial exudates, but it hardly held its own with the old treatment of iodine applications and the glycerin plug, owing to the time and cumbersome apparatus required. But a cumbersome apparatus *alone* is no longer a sufficient excuse to justify us in ignoring the rapid and complete results obtained with *strong* doses, and the other advantages offered by Apostoli's instruments of precision.

I am aware that many assertions of a fact do not carry the weight of a recitation of a series of well-authenticated cases possessing evidences of conscientious reporting and of independent verification. I can only say in self-defence, that I have a series of just such cases in preparation for publication, in which the diagnosis and, afterward, the results were verified in almost every instance by eminent gynecologists.

My experience in the treatment of fibroid growths of the uterus by electricity amounts, in round numbers, to two hundred cases. In that number of cases, not more than five failed to continue the treatment until results could be estimated. Of those who continued treatment and made a fair test of its value, up to the present time but three have failed to obtain relief. One of these was a large, soft, spongy, rapidly growing subperitoneal growth, with a suspicion of malignancy, in a patient who was so sensitive to the treatment as to be unable to receive a satisfactory dose. The second was a marked hæmorrhagic case of a submucous variety, composed of many centres of development, which repeatedly discharged itself in small masses from the uterine canal, until finally the patient became discouraged and ceased treatment. The third case which I have been unable to influence favorably is one of a large, regular subperitoneal variety, which I have persistently labored with by means of the vaginal galvano-puncture with remarkably strong doses. I am unable to account for the stubbornness exhibited in this latter case, and shall recommend surgical interference.

I am fortunate, considering the great number and variety of cases treated, to be able to record no deaths; my results, on the whole, have been exceedingly gratifying. About eighty-four per cent. are symptomatically cured, with an additional per cent. of actual cures. About fifteen cases are still under treatment.

My methods, except in unimportant minor details, are in direct imitation of my friend and master, Apostoli.

There were two varieties of cases that gave me a great deal of perplexity in my earlier work, because I could not find their counterpart in Apostoli's publications. The first was a large interstitial variety of fibroid with a marked hæmorrhagic tendency, in which the patient would not tolerate a strong dose. In these cases the uterine canal is of great depth, and the hæmorrhagic surface of necessity very extensive. In order to check hæmorrhage in such a case, a strong dose is imperative, unless some means

of concentration is employed. Of course, if the ordinary platinum sound electrode is employed, of sufficient diameter and length to cover the whole internal surface of the uterine canal, a current of enormous strength must be employed to get sufficient concentration at any given point to cause coagulation and change of tissue, so as to check hæmorrhage In other words, a certain intensity is required, and the intensity is in direct proportion to the strength of the current and in inverse proportion to the area of the electrode. As it was impracticable to employ a dose of more than from 100 to 200 milliampères in many cases, on account of peculiar sensitiveness, I devised a means of internal concentration, or of limiting the area of the electrode.

A series of experiments, which I have already mentioned in an article read three years ago at the International Congress, proved that a current of twenty-five milliampères was necessary on an average for each square centimetre of internal surface, exclusive of the positive platinum electrode, in order to accomplish coagulation sufficient to check hæmorrhage. Upon that basis I constructed electrodes with a surface of four square centimetres, by means of which definite results were assured, and with which it was unnecessary to employ more than 100 milliampères current, different portions of the canal being treated in turn, at successive applications, until in time all have been covered. These electrodes are easily cleansed by means of a nail-brush and are constructed so that they will not be injured by strong antiseptics. Their flexibility alone is a great recommendation.

The other class of cases fortunately comprises but a small per cent. of all. They are distinguished by great sensitiveness and profuse hæmorrhage at the menstrual period. They tolerate but a small current and are even severely prostrated by the small dose they are able to bear. These cases, of course, cannot be expected to improve unless they are enabled to take a decided dose, and the nervous prostration is so severe when such a dose is forced upon them that it renders the treatment intolerable. A marked hysterical element is often present in these cases. The subsequent prostration is produced no doubt by strong reflex disturbances. I have found that they are readily improved if means are adopted by which powerful doses can be administered at not too frequent intervals, and at the patient's room where she need not be disturbed for six hours following treatment. I, therefore, get the dimensions of the uterine canal, and an electrode is constructed to fit it. I estimate its surface area in square centimetres, and estimate the strength of the current at twenty-five milliampères per centimetre that will be required at each sitting. I then order the patient to repair to her bed one hour before treatment, and to take a full dose of morphine and atropine. If I find, upon turning on the current, the patient will not tolerate the dose required, I ask an assistant to saturate a handkerchief with chloroform and give the patient just sufficient to enable me to attain my object. When that has been reached, the chloroform can be withdrawn, the patient usually being able to stand the electricity after it has once reached its maximum strength. The current is then allowed to operate for ten minutes at the full strength required, when it is gradually withdrawn, and the patient instructed to remain quiet for at least six hours.

If it is not deemed prudent to give the opiate, chloroform alone, of course, can be employed; but I employ the opiate because, as a rule, the patient requires nothing more.

By this method I have repeatedly given doses varying in strength from 200 to 400 milliampères, and prostration seldom follows. The dose is repeated in from six to ten days.

THE TREATMENT OF CHRONIC METRITIS WITH GALVANO-CHEMICAL CAUTERIZATION.[1]

BY G. BETTON MASSEY, M.D.,
OF PHILADELPHIA.

IN regard to this new electrical treatment of the diseases of women, I am of the opinion that a forward movement of vast importance has been initiated. So positive and striking is this progress that a degeneration into a fad is to be feared; but the fear of this should not blind us to important facts. During the last few years electrical science has itself been revolutionized, and it would be strange indeed if our better knowledge of it did not lead to the better application of this force to the medical arts.

Most authors have referred but little to one class of conditions in which I regard the galvanic current as possessed of an unique value. I allude to chronic inflammation of the uterus or of the endometrium. Theoretically, nothing could be better. In a convenient, clean, and controllable form we have an agent that will act as an alterative to the diseased membrane, and at the same time reduce interstitial hypertrophy by promoting both absorption and contraction. What other remedy promises as much?

In practice I have found that facts coincide very closely with this theory. I will give several brief illustrations:

A young married woman had been ill two and a half years, dating from a miscarriage. The symptoms were those of a chronic metritis with copious

[1] Read before the New York Academy of Medicine, Section in Obstetrics and Gynecology, November 27, 1889.

leucorrhœa from a capacious cavity three inches in depth. Fifty milliampères negative were applied intra-uterine for three minutes. Three days later she was better than for many months. After a second application the cavity decreased to the normal depth, and after a third she was completely cured.

Another case was that of a lady, aged thirty-one, who had been suffering from leucorrhœa and pain since a miscarriage, two years before. Examination showed a slightly lacerated os and a hypertrophied uterus pouring forth an abundant purulent discharge from a three-inch cavity. Two intra-uterine negative and one positive cauterization were given with a current of fifty milliampères, resulting in a prompt and complete cure.

Another case presented symptoms of both chronic metritis and parametritis. This woman was seen at the Howard Hospital Clinic in September last, with the ordinary symptoms of chronic metritis dating back three years to a miscarriage. The uterus was enlarged and indurated with a three and a half inch cavity and a peculiar hypertrophy of the anterior lip. There were also decided fixation and tenderness on the right. She was given four intra-uterine cauterizations varying in strength from fifteen to forty milliampères. The result was a reduction of the cavity to two and a half inches plus, and the complete disappearance of a host of annoying symptoms.

In simple endometritis or uterine catarrh, galvanic currents locally applied are practically infallible. I have never seen a case resist them. The current strength need not exceed ten to thirty-five milliampères, using the bare intra-uterine electrode and an external indifferent pole of proper size. The choice of pole is governed by the presence or absence of menorrhagia, the positive pole being always used with this complication. When the endometritis is associated with slight cervical lacerations, it will usually be found unnecessary to perform the operation for repair, as all symptoms disappear under this treatment, leaving the patient practically well, even though a slight irregularity in the cervix remains.

REMARKS UPON THE USE OF ELECTRICITY IN THE TREATMENT OF FIBROID TUMORS OF THE UTERUS.[1]

BY ALEXANDER J. C. SKENE, M.D.,
OF BROOKLYN, NEW YORK.

IN estimating the value of electricity in the treatment of fibromata I have, of necessity, been guided by the opinions of others more than by my own observations. Owing to the extremely conflicting testimony of those who have expressed themselves, it has been very difficult to get at anything definite.

One class of men has condemned this treatment without mercy. Another class has obtained the most perfect results—all that could be desired, in fact—and still another class has had an intermediate experience. They have been able to relieve their patients of most or all of their symptoms, and have diminished the size of the tumors or retarded their growth.

I have accepted the testimony of this latter class of witnesses because it apparently contained the most truth, and also because it agreed with what little experience I have had in my own practice. More than that, I have observed that those who avoid the extremes of praise and condemnation are gaining in numbers.

Time will not permit a full review of the arguments employed by those who are opposed to this treatment of fibromata, but it may be said that the strongest opponents are those who know least about electro-physics and the therapeutic use of electricity. They have not thoroughly tried it in practice, but have theorized about it and insisted that from the nature of electricity it could not affect neoplasms, forgetting that, in this, electricity is like many other therapeutic agents which produce most valuable effects, while we do not know how such effects are produced.

It has also been claimed that this agent is dangerous, but that has been fully met by the fact that all the benefit can be obtained without taking the risks that were at one time supposed to be unavoidable.

Scoffing and ridicule have been indulged in by a few, but they are signs of weakness in those who indulge in such methods of wrestling with questions in science, and may be passed without notice.

Perhaps the most important question in the whole discussion is the relative merits of this and other methods of treatment. The claims of hysterectomy and the removal of the ovaries for fibromata have been urged with great vigor by those who are strongly addicted to surgery. There is, however, no evidence that this kind of surgery is safer or surer in its results than electricity.

By a curious misuse of facts, it has been made to appear that surgical treatment has advantages which it does not possess. Many cases are reported cured when they are simply relieved from the immediate effects of the fibroma and when, in fact, they are in worse health than before the operation.

I have tried to get records to show that more cases have died from removal of the uterus and ovaries for the cure of fibromata than have died from fibromata without treatment of any kind. If such are the facts—and I believe that the records of New

[1] Read before the New York Academy of Medicine, Section in Obstetrics and Gynecology, November 27, 1889.

York and Brooklyn would show them to be—surely surgery does not compare favorably with electro-therapeutics.

Add to this the cases that suffer ill-health after losing the ovaries and uterus, and the records of surgical treatment are not very largely in the interest of patients, though they may be in the interest of surgeons.

Certainly, the claims of electro-therapeutics are too well sustained to be put aside by any adverse arguments which have been advanced. In fact, the record of the treatment of uterine fibromata by electricity is remarkably good considering the short time that it has been properly used, and this leads to the hope that when it is better understood and more wisely employed it will gain more confidence.

Up to the present time it has, in its immature state, been competing with surgery, which has had the advantages of being perfected by long experience.

Great progress has been made within a short time. In a recent discussion in the Academy of Medicine of Paris it was shown that strong currents are not necessary; neither is it necessary to puncture the tumor in order to get good results. This enables us to avoid all dangers, hence is a great improvement in the art.

The science of electro-therapeutics has also been advanced greatly by the discovery of the action of the electric current upon tissue, as demonstrated by Dr. Buckmaster and confirmed by Dr. Van Cott, a demonstration which ought to silence all who have argued that such effects were impossible.

MEDICAL PROGRESS.

The Nutritive Value of Boiled Milk.—That the sterilization of milk, however important, is not without its disadvantages, has been shown by Randnitz and others (MEDICAL NEWS, November 30, 1889). To determine the comparative assimilability of proteids and fats from boiled and non-boiled milk, DR. EVSEVY V. VASILIEFF, of St. Petersburg (*St. Petersburg Inaugural Dissertation*, 1889, No. 33, p. 35), has undertaken a course of most careful experiments on six healthy young men, aged from eighteen to twenty-three years. Eacn experiment lasted six days, during three of which the men received raw milk, and during the other three boiled milk, the daily amount of the article in either case varying between 1850 and 4200 cubic centimetres. The following are the conclusions deduced by the author from his very instructive researches:

1. The assimilation of nitrogenous ingredients from boiled milk is invariably less than that from the raw article. In the case of raw milk the average percentage of non-assimilated nitrogen amounts only to 7.05, the maximum to 7.62, and the minimum to 6.42; while in the case of boiled milk the respective figures are 8.18, 8.79, 7.76.

2. The same holds true with regard to the assimilation of fats. When fat is ingested in a raw state, the average percentage of non-assimilated fatty acids is 3.89, the maximum 4.85, and the minimum 2.88. In the case of boiled milk, however, the figures rise to 6.01, 6.99, and 4.53 respectively.

3. Boiling seems to affect especially the assimilation of the fats of milk, since the percentage of fatty acids in relation to the total quantity of dried fæces in those fed on boiled milk is considerably larger than in those fed on non-boiled milk. In the former case, fatty acids constitute 19.03 per cent. of the total amount of dry fæces; but in the latter, not more than 16.81. In other words, when a person ingests his milk boiled, every 100 grammes of his dry fæces contain a surplus of fats amounting to 2.22 grammes.

4. Therefore, as regards its nutritiousness, boiled milk represents a decidedly inferior dietetic article, compared with raw milk.

6. As far as proteids are concerned, the difference in their assimilation may find some explanation in Dr. I. Schmidt's researches (*Moscow Inaugural Dissertation*, 1882), according to which, under the influence of boiling, cow's milk undergoes important chemical changes, nearly all the albumen and a part of the casein being transformed into hemialbumose. Schmidt's analysis proves that raw cow's milk contains 8.55 per cent. of casein, 8.4 of albumen, and 6.1 of hemialbumose. Under the influence of ten minutes' boiling, the proportion of casein sinks to 7.59 per cent., that of albumen to 0.7, while that of hemialbumose rises to 23.4.—*Provincial Medical Journal*, January, 1890.

Local Application for Pharyngitis.—The following prescription for acute pharyngitis is published in the *Revue de Thérapeutique*, January 1, 1890:

R.—Sodium borate } . of each 30 grains.
Sodium chlorate }
Glycerin . . . . . 2 drachms.
Honey . . . . . 6 " —M.

To be applied with a camel's hair brush.

Menthol in the Vomiting of Pregnancy.—DR. WEISS advises the administration of menthol in the vomiting of pregnancy, a drug which was first recommended for this condition by Gottschalk. The following is the formula used by Weiss:

R.—Menthol . . . . 15 grains.
Alcohol . . . . 5 fluid drachms.
Syrup . . . . . 1 fluid ounce.—M.

One teaspoonful to be given every hour.—*Therapeutische Monatshefte*, January, 1890.

Intravenous Injections of Quinine in Malaria.—BACELLI advocates the use of intravenous injections of quinine in the pernicious forms of malarial poisoning. The solution he employs consists of:

R.—Quinia hydrochlorate . . 15 grains.
Sodium chloride . . . 1½ "
Distilled water . . . 154 minims.

Before using the solution on patients, he experimented with animals and satisfied himself that there was no danger to be apprehended from the method. With patients suffering from the severe malarial fevers the results, he

claims, are brilliant. To secure an absolute curative effect, 15 grains of the quinine salt were necessary, though smaller doses proved beneficial. In some cases, Bacelli is confident that he has saved life by the prompt employment of this method of treatment.—*Centralblatt f. d. gesammte Therapie*, January, 1890.

Paraldehyde in the Treatment of Tetanus.—In the Moscow *Meditzinskoïe Obozrenïe*, No. 21, 1889, DR. VARNAVA E. IGNATIEFF, house physician to the Jauzsky Hospital for Laborers, Moscow, reports two exceedingly severe cases of tetanus cured by paraldehyde. The first case is that of a peasant girl, aged fourteen years, who was admitted on the fourth day of the disease. For the first ten days (from the fourth to the fifteenth day of symptoms) she was treated with chloral, one drachm daily. The patient's state steadily growing from bad to worse, paraldehyde was resorted to. Marked improvement began almost immediately. About the thirty-third day of the disease, general spasms ceased altogether. About the thirty-ninth, trismus disappeared. On the forty-fifth, the girl got up, being practically well. On the sixty-eighth, she was discharged in a most satisfactory state. The drug was given both by the stomach and rectum, the total daily dose varying from one to two and a half drachms. In all, the patient took twenty-five and a half drachms in nineteen days, an average of eighty grains a day. The history of the second case is much the same, the woman being discharged perfectly well on the forty-third day after the commencement of the disease.—*Provincial Medical Journal*, January, 1890.

The Treatment of Anal Eczema.—It is a well-known fact that eczema about the anus and genitals of both sexes frequently resists all the well-known remedies that speedily cure the same affection on other portions of the skin. According to UNNA (*Monatshefte f. praktische Dermatologie*, No. 9, 1889), this obstinacy to treatment is attributable in part to the proximity of the disease to a mucous surface and its irritating discharges; in part to its rich supply of nerves, rendering itching so pronounced a symptom that scratching and its effects make most of the remedial applications useless; finally, because of the difficulty in applying remedies to this region.

The majority of such cases may be cured by the application of well-adapted bandages to which lotions or ointments have been applied, by cauterization with carbolic acid or corrosive sublimate, the use of cocaine, or especially with fomentations of very hot water.

When, in spite of all these remedies, the eczema becomes aggravated, the skin assuming, through the growth of connective tissue and epithelial proliferation, a cicatricial and warty appearance, the itching becomes unendurable, and the patient, from loss of sleep, physically and morally weakened, one should not hesitate to resort to local or general anæsthesia, and with a broad Paquelin cautery slowly burn the affected parts, so that, were the proper remedies not applied immediately, a burn of the second degree would result.

Before the anæsthesia is over, apply either a five per cent. solution of borax, with or without the addition of cocaine, Carron-oil to which two per cent. of carbolic acid is added, or a two per cent. resorcin solution. The following formula is especially useful:

R.—Linseed oil Lime water Oxide of zinc Chalk	.	of each 5 parts.
Iodoform	. . . .	1 to 2 parts.—M.

By means of the before-described treatment one can frequently, in fourteen days, cure an eczema of months' or years' duration.—*Journal of Cutaneous and Genito-urinary Diseases*, January, 1890.

Massage of the Eyes.—PFALZ, in the *Deutsche medizinische Wochenschrift*, recommends ocular massage as a valuable method of treatment in various diseased conditions of the eyes. He employs it by applying to the surface of the eyelid a salve, the nature of which will vary with the disease, and then rubs the eyeball in a radiating or circular direction. The physiological action of massage consists in stimulation of the circulation, in the absorption of pathological products, in irritation of the nerves, and in the freeing of the nerves from the compression exercised upon them by the pressure of pathological products. Massage is especially adapted to those parts of the eye which are directly accessible, but the iris and ciliary body can also be influenced by it. Corneal opacities, the remnants of previous inflammations, are especially amenable to this method of treatment. Also parenchymatous keratitis, but only in the later stage. It is also applicable in cases of chronic pustular conjunctival affections, vernal catarrh, dry catarrh, chronic iritis, and blepharitis marginalis.—*Archives of Ophthalmology*, December, 1889.

Trichinæ in Swine.—PROFESSOR E. L. MARK has recently published the results of the examination of 3064 hogs raised in the vicinity of Boston, Massachusetts (*Report of Massachusetts State Board of Health*). The examination extended over the five years, 1883 to 1888. The results show that 14.07 per cent. of the males and 10.61 of the females were infected with trichinæ. Similar examinations of Western hogs have shown only from two to three per cent. to be infected. Professor Mark reaches the conclusion that this difference is probably due to the character of the food given to those raised in the vicinity of Boston and presumably in the vicinity of other large cities. Of the fifty-six raisers of the hogs examined by him, fifty-one fed city offal. The source of the infection he believes to be in the uncooked meat found in kitchen garbage. It would be interesting to know the condition, in this respect, of the large number of hogs fed upon this food in and about the other large cities.—*Brooklyn Medical Journal*, January, 1890.

Insanity from Traumatism.—DR. CHRISTIAN, physician to the Charenton Asylum, discusses in *Archives de Neurologie*, July and September, 1889, the relations between injuries to the head and insanity. He comes to the conclusion, not only that insanity may be the immediate result of fractures of the skull and concussion of the brain, but that it may follow as a consequence of injuries to the head received many years before its outbreak, from which recovery has been, apparently, perfect. Considering the frequency of such accidents, especially in the earlier years of life, the proof he furnishes of the latter proposition does not seem to be altogether com-

plete, although, probably, no one will deny the possibility of such cases.—*American Journal of Insanity*, January, 1890.

Jaundice during Pregnancy.—In a paper upon "Jaundice during Pregnancy," in the *American Journal of Obstetrics*, January, 1890, DR. JOHN T. WINTER concludes that every case of jaundice occurring in pregnancy should be looked upon as serious, jeopardizing both mother and child. It would seem probable that a simple catarrhal jaundice occurring from exposure to cold, from indigestion, from pressure, etc., is changed for some reason into a disease of more malignant character, terminating not infrequently in abortion, coma and convulsions, and proving fatal in a majority of instances to both mother and child.

The death of the fœtus and its expulsion should not surprise us, when we remember that the only source from which it can obtain sustenance is loaded with poisonous elements; and, as the death of the mother rarely occurs until several hours after the expulsion of the fœtus, there seem good grounds for believing that her death is due in many instances to shock, caused by labor, on a system already reduced by impaired nutrition and impoverished blood.

Intubation versus Tracheotomy.—PROFESSOR RANKE, in the *Internat. klin. Rundschau*, November 10, 1889, compares intubation and tracheotomy in the treatment of diphtheritic stenosis of the larynx thus:

1. Intubation is successful in many cases, and is a decided addition to our methods of treatment.

2. Tracheotomy will never be entirely superseded by intubation.

3. The methods are in no sense rivals, but are supplementary to each other.

4. As a rule, intubation should be first attempted, and tracheotomy be resorted to if the former is unsuccessful.

Paste for the Relief of Toothache.—

R.—Arsenious acid, Hydrochlor. of cocaine } of each 15 grains.
Menthol . . . . . 3 "
Glycerin sufficient quantity to make a paste.—M.

A small portion of this is to be packed into the cavity. —*Revue de Thérapeutique*, December 1, 1889.

A Case of Multiple Neuritis due to Arsenical Poisoning.—DR. MCPHEDRAN publishes the following case, which is clearly one of arsenical neuritis, in the *Canadian Practitioner*, January, 1890:

T. S., aged fifty-eight; English; no occupation; personal and family history contain nothing of importance.

In April, 1889, he noticed a hard swelling on the left side of the neck behind the angle of the jaw. It grew rapidly. In May he went to a so-called "cancer doctor," who applied a plaster, leaving it on for two days, then a poultice for two more days, and so on alternately for about two weeks. The plaster caused great pain, the poultice less. Before the completion of this treatment he noticed that his legs were becoming stiff and numb, and that painful sensations occurred in them. He was soon unable to walk. The hands became affected shortly after the feet, though less severely.

He entered the Toronto General Hospital, under Dr. McPhedran's care, June 29, 1889. He presented the appearance of a quiet, temperate man. His legs and feet were almost completely paralyzed, greatly wasted, and the muscles very flabby; the skin deeply pigmented and dry, with some fine desquamation; free scaling on soles of feet. Anæsthesia of the legs was distinct, though they were sensitive to certain impressions, as, *e.g.*, drawing the finger-nail quickly along the sole of the foot. Cold was readily perceived; but heat was not felt, except when great, and then gave the impression of cold. Knee-jerk was absent, as were also all the reflexes, both superficial and deep. Without the aid of sight he was unconscious of the position of the legs. There was great pain in them, especially at night, an anodyne being required to enable him to sleep.

The hands were similarly affected, but to a much less degree. Owing to the anæsthesia and paresis, he had been unable to feed himself for some days.

To the faradic current there was no response in the forearms, hands, legs, or feet; a strong current gave a weak contraction in the arms and thighs.

There were no bowel or bladder symptoms. He said that he had had no rash of any kind.

Potassic iodide was given and the bowels kept freely open by salines. He began to improve by the 1st of August, and toward the end of September was able to stand alone for a minute or two. He has steadily improved since then, and is now able to walk a short distance. On account of the anæsthesia, which is still considerable, he cannot stand or walk with the eyes shut. The muscles have become quite large and firm, and the pigmentation has disappeared; the skin is fairly soft and moist. The reflexes are still wanting. To use his own words, he feels as if the tendo Achillis and the flexors of the fingers were too short, and should be let out a notch or two. This, is probably due to the greater weakness of the extensors as compared with the flexors, a condition easily shown to be present by testing the strength of the two.

Faradic irritability is completely restored in the forearms and hands, but is still absent in the legs and feet.

As to the cause of the paralysis in this case, there can be no doubt; nevertheless it is to be regretted that the urine was not examined for the presence of arsenic. Alcoholic neuritis is excluded by the absence of a history of intemperance, nor is there a history of rheumatism or exposure.

Prescription for Cystitis.—To render the urine aseptic in cystitis and gonorrhœa, the following is recommended in the *Gazette de Gynécologie*, December 1, 1889:

R.—Sodium borate . . . . 1 part.
Syrup of raspberry . . . 3 parts.
Infusion of lactucarium, Infusion of linden flowers } of each 8 " —M.

One tablespoonful every two hours.

or

R.—Benzoic acid . . . . 1 to 2 parts.
Glycerin . . . . . 5 parts.
Simple elixir . . . . 75 " —M.

One tablespoonful every two hours.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

THE TREATMENT OF CHLOROSIS.

A CONVICTION, long growing, is now mature, that the treatment of chlorosis has been, hitherto, too direct. Paradoxical as it may seem, this error is the natural consequence of exact methods of diagnosis, and adds another link to the long chain of evidence that personal experience, based upon clinical observation, can never be eliminated from successful medical practice.

It was no sooner proved that the essential pathological element of chlorosis was a deficit of iron in the blood, than it was assumed that the control of this affection was absolutely in the hands of the physician. The diagnosis once made, the treatment followed as a matter of course, and was applied to the disease without any regard whatever to the individual.

The success which attended this line of treatment, while undeniably great, fell far short of the expectations of its most ardent advocates. Cases of chlorosis were now and then encountered which were heroic in their refusal to assimilate iron. Something was evidently wrong, and the fault was supposed to be either in the preparation employed, or in its dose. Some held with Trousseau that the best results were to be obtained with insoluble preparations, such as iron filings, while others vaunted the efficacy of the soluble salts of the metal. By some practitioners, as much iron as existed in the blood of a healthy man would be administered in one day, while others contended that such a practice was absurd, since, in health, only minute quantities were absorbed with the ingested food. In a word, the attention of physicians was almost exclusively centred upon the medicinal treatment of chlorosis, the hygienic management of this disorder of nutrition being, as a rule, altogether overlooked.

These remarks have been suggested by the report of a number of well-marked cases of chlorosis successfully treated by enemata of defibrinated blood. M. Antiq (*Lyon Médicale*, No. 44, 1889), the originator of this method, claims remarkable success from its employment, and believes that it fulfils, more successfully than any other, the three indications in the treatment of chlorosis, namely: 1. Restoration of iron. 2. Restoration of oxygen. 3. Restoration of the salts of potash and of the chlorides.

With no intention of discrediting these observations, we venture the prediction that this somewhat *outré* method of treatment will be found of limited application, for, like the ordinary mode of administering iron, it is, so to speak, too direct.

The greatest success in the treatment of chlorosis will be achieved by those who bear in mind that, whatever the predisposing cause of this nutritive disorder may be, its exciting cause may vary in each individual. Each case, therefore, must be treated on its own merits, or, to be precise, on its own demerits. Of general application are hygienic measures, such as outdoor exercise on foot, on horseback, sea-bathing, massage, etc. The importance of such measures is insisted on by Peter in a recent lecture on this subject.

When it is recalled that the merest trace of iron which is present in mothers' milk is sufficient to supply the wants of a rapidly growing organism, it becomes evident that the cause of chlorosis is something which interferes with the assimilation of that metal. This obstacle may be best removed by a general or indirect method of treatment, of which the details may vary in each case. Iron is found, by experience, to be necessary in all cases, but it is useless in many unless combined with the general hygienic measures to which allusion has been made.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Section in Obstetrics and Gynecology.

J. E. Janvrin, M.D., in the Chair.

Stated Meeting, November 27, 1889.

DISCUSSION ON THE USE OF ELECTRICITY IN GYNECOLOGY.

The following papers were read:

General Observations on the Use of Electricity in Gynecology, by Dr. A. D. Rockwell, of New York (page 82).

The Treatment of Certain Pelvic Tumors by Galvano-puncture and Drainage by the Vagina, and Intra-uterine Galvanization, by Dr. Augustin H. Goelet, of New York. (page 84).

The Galvanic Treatment of Uterine Fibromata, by Dr. E. L. H. McGinnis, of New York (page 88).

Notes Regarding the Treatment of Fibromata by Electricity, by Dr. A. H. Buckmaster, of Brooklyn (page 91).

The Value of Bi-polar Faradization in Gynecology, by Dr. A. Lapthorn Smith, of Montreal (page 93).

In the discussion which followed the reading of these papers:

Dr. P. F. Mundé, of New York, said that for a number of years he had been much interested in this subject of electrical treatment, and believed he had had ample opportunity to become acquainted with its practical working. He could speak most decidedly in favor of electricity as a therapeutical agent in gynecology, and had published his views on this subject in an elaborate article several years ago. He had seen more benefit derived from galvanism than faradism in gynecological practice. He had also found that mild currents used for a long time are, as a rule, more efficacious than strong currents employed for a short time. He used a Leclanché forty-cell battery. For ordinary purposes he used a small meter registering only twenty milliampères. He had another which registered 500 milliampères. This he had used a few days ago in treating a fibroid, and had found it faulty and untrustworthy.

With galvanism, placing the positive electrode next to the sensitive part in the pelvis, or on the abdominal wall, he had obtained excellent results in relieving the pain of chronic pelvic peritonitis. In old cases of inflammation with adhesions, with more or less pain in the ovaries and tubes, he had found that the tri-weekly administration of electricity, with the positive current internally, was a decided benefit after a few months of treatment. On the other hand, a number of patients, after several months of such treatment, had received no appreciable benefit whatever, and laparotomy had to be performed. This showed that electrical treatment was not suited to these particular cases. However, he deemed it proper in all circumstances to give patients every opportunity for possible benefit from electricity before subjecting them to a radical operation which, by whoever performed, could never be without an element of danger.

In obscure pelvic pain, due to an inflammatory deposit unrecognizable by digital examination, extending down the sciatic or crural nerves, he had seen instant relief follow the use of electricity after other treatment had failed. While he relied on electricity, and had found it of great benefit, especially in relieving pain, he thought it might be carried too far. He considered the length of time necessary to achieve satisfactory results was a great drawback to the use of electricity. If it was clear, however, that some good was being done, the time was, of course, not lost.

As to the milliampèremeter, though he had two, he was by no means satisfied that it was at all necessary, and was inclined to look upon it as a sort of plaything. When using galvanism for the relief of pain, the sensations of the patient, he thought, were a sufficient guide as to the strength of current to be employed; but when using the current in anæsthetized patients or for galvano-puncture, it was necessary to know exactly the strength.

The faradic current he had found very useful in amenorrhœa, intra-uterine faradization being employed three times a week for this purpose. He had used electricity but once in extra-uterine pregnancy, the interrupted galvanic current being the one employed. He had cured the patient, after nearly killing her by the shock. In pyosalpinx and pelvic abscess, laparotomy and drainage were certainly to be preferred to galvano-puncture. As to uterine fibroids, he had very decided views. He considered that the value of operative treatment in this class of cases was over-estimated. Out of 123 cases coming under his observation, about 50 per cent. had required no treatment whatever. 62 had required treatment, but only 8 of this number, in his opinion, had required Apostoli's method, and 4 others called for galvano-puncture. Apostoli's plan of treatment covered only the intra-uterine use of galvanism, with the clay electrode on the abdomen, the galvano-puncture being not strictly his method.

He had used the Apostoli treatment eight times in three years, and he could honestly say that while he believed it efficient for the removal of pain and the checking of hæmorrhage, and admitted that the patients felt better for its use, not a single tumor which had come under his notice had been much reduced in size. By galvano-puncture he meant puncture through the vagina, and this, in his opinion, was the ideal treatment for the cure of uterine fibro-myoma. The four cases in which he had employed it had been absolutely cured—that is, the tumors disappeared entirely, not a vestige being left. In one of the cases a single puncture gave rise to sloughing, and this sloughing itself destroyed the growth; in the others the cure was directly due to the effects of the electrical treatment. He was, therefore, a decided believer in galvano-puncture. At the same time, he believed it had its risks, and he thought it should never be employed at a physician's office.

Dr. Franklin H. Martin, of Chicago, exhibited a portable battery, and made some remarks upon the use of electricity in the treatment of certain pelvic diseases of the female (page 95).

Dr. G. Betton Massey, of Philadelphia, then said that Dr. Goelet's canula might itself answer as an electrode, which would have the special advantage of allowing the gas to escape through it. In speaking of the treatment of pelvic cellulitis, he said that in one case he had been using simple vaginal applications of the strength of seventy-five milliampères with very good

results. In the use of electricity in gynecological practice he thought too much attention was paid to antiseptic washes. These were not necessary, he thought, if perfectly clean and aseptic electrodes were employed. Dr. Massey agreed with Dr. Lapthorn Smith in his explanation of the action of bi-polar faradization, but said he could not agree with him as to the use of the coarse wire as contrasted with that of the fine.

He could not agree with Dr. Mundé in his opinion of the milliampèremeter. He considered it of importance if more than five or six cells were employed. As to the sensations of the patient furnishing a guide for the strength of the current, he had seen as active a sensation caused by fifteen milliampères with the negative pole in the uterus, as resulted from 350 milliampères in other cases. In regard to the use of electricity in pyosalpinx, he had met with one instance in which the treatment for endometritis excited a flow of pus. He had reported the case to the Obstetrical Society of Philadelphia, and the patient had since then been quite well. The passing of the electrode in the direction of the left cornua of the uterus seemed to have been efficient in causing the result named.

DR. BUCKMASTER read some remarks, prepared by Dr. A. J. C. Skene, of Brooklyn, who was prevented from being present (page 99).

DR. H. J. BOLDT, of New York, after speaking of the theory of the bi-polar action of the current on the tissues, went on to say that those gentlemen who absolutely denied any value to electricity were those who had never given it an honest trial. They had no right to operate on any patient until electricity had been given a thorough test. That it would not, however, in every instance even alleviate the symptoms he thought was perfectly true. As to pyosalpinx, he thought that these cases were cured when the tubes were cut out, and not otherwise. When the tubes were distended and the uterine extremities were closed, or when the tubes were agglutinated, what could be expected from electricity? All that could be done then was to remove the tubes by laparotomy. But as long as the calibre of the tubes remained patent, it was well to try everything. Many mistakes, he said, were made in diagnosis, and he thought it was not advisable to be too enthusiastic.

DR. GOELET in closing the discussion, said he had cured at least thirteen cases by galvano-puncture, which otherwise could not have been relieved except by laparotomy—that is to say, the patients would otherwise have been mutilated; and he thought it was only right to try to cure these patients before mutilating them. By emptying the tubes and the use of the current subsequently, the tubes might be rendered patent. He thought that the pus could be first emptied, and then the removal of the cause of the accumulation of the pus effected. The resolution of the proximal end of the tube could be produced by galvanism of the endometrium, and he was very glad to hear that in this particular his experience had been confirmed by Dr. Massey in the case related. He did not think that we ought to say that the removal of the tubes was a cure of pyosalpinx. It was a mutilation, and not a cure, and in many cases, indeed, the patient's condition was more embarrassing after the operation than before.

He thought that many of the failures with electricity which Dr. Mundé said he had met with were to be attributed to the fact of his having used his currents too weak. Then, again, he thought that Dr. Mundé had made a mistake in regarding the milliampèremeter as a plaything. Many women would bear intense pain and say nothing about it, and electricity might be thus administered in dangerous doses. It was also impossible to estimate the particular resistance of the tissues in every case; and, for these reasons, the meter was always an important auxiliary.

THE CHAIRMAN asked Dr. Goelet whether his experience of intra-uterine galvanism had demonstrated to him the fact that an occluded tube had become patulous again, and was performing its function in a normal manner. He said that, of course, the fact of fecundation occurring did not imply that both tubes were functionating.

In reply, DR. GOELET said that he could only assume that complete recovery had ensued from the fact that all symptoms were completely removed, that menstruation became normal, and that there had been no reaccumulation in the affected tube.

CORRESPONDENCE.

LONDON.

The Conveyance of Infection by Medical Men; Clinical Instruction in Fever Hospitals; The Muzzling Order.

To the Editor of THE MEDICAL NEWS,

SIR: There has been a discussion in the columns of one of our leading daily newspapers during the last few weeks in regard to the conveyance of infection, chiefly scarlet fever, by medical men. The possibility of this none would deny; but that it often occurs seems more than improbable. I have made inquiries amongst some of my friends in large practice, and letters have appeared from practitioners in the *British Medical Journal* and elsewhere; and I gather that most medical men do take all reasonable precautions when attending an infectious case to prevent their carrying the infection elsewhere. There is a general consent that, if possible, the scarlet fever patient should be visited at the end of the day's round, or, when that is not possible, at the end of a round; and that a doctor who has any midwifery cases on hand should not attend scarlet fever cases, and *vice versa*. Of course, in country districts it is not always possible for a man to hand over his patients to a professional brother. All the writers are agreed that on entering the room in which the patient is, the doctor should put on a waterproof or alpaca cloak, or one of some smooth material, which he is to take off on leaving the room and leave at the house for use at his next visit. He should handle the patient as little as possible, especially during the desquamative stage. All instruments used, such as stethoscopes, thermometers, etc., should be washed in a strong solution of carbolic acid. The doctor should wash his hands in some disinfecting solution before leaving the room, and on leaving the house should, if possible, walk home, or if too far, should drive in an open vehicle, or, at any rate, have the windows of his carriage down. On his arrival at his own house he should subject himself to a more thorough process of disinfection; and if he possesses a steam spray, he cannot do better than set it going and spray himself all over

with carbolic acid; especial care should be taken to disinfect the hair, and even the boots should not be forgotten. One writer suggests the advisability of wearing a mackintosh cap whilst in the sick-room, and the idea seems to me a good one. The discussion was started originally by Miss Cobbe, who is well known for her undying antipathy to medical men in general and vivisectors in particular.

Curiously enough, the subject of scarlet fever has been before the public from another point of view. It has long been a standing disgrace to us in London that we had almost no provision for giving instruction to students in the diagnosis and general management of infectious cases, but at last a prospect of remedying this unfortunate state of affairs has arisen. The fever hospitals are under the control of a body known as the Metropolitan Asylums Board, and a conference is now being conducted between representatives of that Board and the College of Physicians to arrange the details of a scheme by which the fever hospitals shall be thrown open for the purposes of medical study. This is not only of great importance in itself, but also as paving the way for another much-needed reform. Within the last twenty years or so there have sprung up in various parts of London many large hospitals connected with the workhouse, and under the control of the various parishes; they contain an amount of clinical material the value of which is simply incalculable, for all cases of chronic disease amongst the poor eventually drift there; but they are not as yet available for clinical purposes. There is, however, good reason to hope that as a remote result of the present outcry for instruction in fever cases the admission of students to the infirmaries will ultimately be granted.

Your readers are possibly aware that since August we have had a muzzling order in force in London with most happy results as regards rabies and hydrophobia; but, of course, there are opponents to it, as to everything that is for the public good, and a few evenings ago a public meeting was called by the Dog Owners' Association to agitate for the repeal of the muzzle. It was a happy choice of a name when the society dubbed itself the Dog Owners' Association, for it certainly has no claim to pose before the public as doing or having done anything to befriend dogs. However, we may let that pass. The Association for the Prevention of Hydrophobia, of which Professor Horsley is one of the leading spirits, issued an appeal inviting persons to come and support an amendment that was to be proposed by Professor Horsley. When the meeting took place the room was densely filled, but it was soon evident that the conveners of the meeting would be in a decided minority; a considerable number of well-known physicians and surgeons were present, and a liberal supply of medical students. Professor Horsley made a most excellent speech, though, of course, it did not convert a single member—such a thing never does happen—but his facts were most clearly stated, and his attack on the case was, for his opponents, simply overwhelming. He concluded his speech by quoting M. Pasteur's dictum, that hydrophobia and rabies ought to be and could be completely stamped out of the British Isles by police regulations. I think after the experience of this meeting, we shall not for some little time hear much about an agitation against the muzzling order; if we do, I have no doubt that Professor Horsley will be again to the fore, and will win another signal victory.

MUNICH.

(*From our Special Correspondent.*)

To the Editor of THE MEDICAL NEWS,

SIR: Munich is more noted in medicine for her distinguished men than for her popularity as a centre for foreign students. The names of Pettenkofer, Nussbaum, Voit, Ziemssen, Winckel, Bollinger, Oertel, and Vogel make the medical faculty of her university famous. These men are held in great veneration by the people of Munich, who take pleasure in including them among the celebrities and are eloquent in praise of their public services. The present advance here in sanitary precautions, which has done so much in improving the public health, is due to Pettenkofer; and to Nussbaum the city looks with gratitude on account of his labors extending through so many years, and including such a rich dispensation of public charities.

Besides good instruction Munich offers great advantages in her clinical material. The great amount and variety of this are shown by the following list of cases in one of the daily clinics, that of November 25th, at the Frauenklinik:

Three patients with ovarian tumors, brought before the class for the purpose of instruction in diagnosis; a case of partial prolapse of the uterus; a case in which a rise of temperature without evident cause, in the fifth day after labor, presented a question for diagnosis; a case in the second stage of labor, in which the presentation ot the child and the patulency of the os as labor progressed were demonstrated; and a collection of fresh specimens of fœtus immaturus and præmaturus, including specimens from the fourth to the ninth months.

It is to be remarked incidentally from this that the dangers from infection are here regarded in an optimistic light; for all the patients are brought into the clinic at once. In this clinic the instruction is individual, each student out of a limited number has a patient assigned to him; while the instructor enlarges upon the case for the benefit of the class. The gynecological department of the Frauenklinik, however, is by no means its only important feature, as the average number of confinements during the year is eight hundred.

Professor Winckel operates at this time in the year at eight in the morning, and during the summer at seven. On November 22d I saw him perform a laparotomy for a cyst of the left ovary. Both ovaries were removed, and the stumps stitched to the anterior abdominal wall, to overcome a retroflexion of the uterus. This appeared to be an extremely radical procedure, for the uterus had been displaced by the large tumor in the abdomen, and by trusting to the chance of replacing the uterus after the operation the operator could have avoided the complication arising from such forcible traction on the stumps by the abdominal wall. He performed the operation sitting before the patient in the position occupied by the operator in a lithotomy. The patient was placed on a low iron table with her legs extended on either side of the operator and supported by iron rests. By this means the operator is brought near the abdomen without the inconvenience of stooping. At the same time such

a position makes it difficult for him to seize the ovaries when the abdominal wall is thick, or when the ovaries are held down by adhesions. This objection, however, is partly overcome by the position of the patient, which, on account of the extension of the thighs puts the anterior abdominal wall on the stretch, and brings the contents of the abdomen near the surface. The operating table offered an advantage of which we, in our appliances, are certainly destitute — that is, the means of permitting the dressing to be applied *without* lifting the patient. The part of the table beneath the small of the patient's back is hung on hinges, so that it can be let down, thus allowing a space for the bandage to be carried around the body.

To a stranger, Nussbaum's clinic is exceedingly interesting. To speak of his age and the consequences of his life of hard work as infirmities, would be a profanation. His voice, his genial manner, his power of expression warm his listeners into enthusiasm almost before they are aware of his presence. He operates every morning at eight and appears punctually on the hour, wheeled into the arena by a special porter of the hospital. He operates sitting before a low table, for he is not able to stand. I saw his clinic of November 28th, in which he operated on three cases. On November 27th he performed three operations; on the 26th a supra-pubic lithotomy; on the 25th an amputation of the breast for carcinoma with involvement of the axillary glands; on the 24th another supra-pubic lithotomy. Up to that time, since November 3d, he had performed six such operations. This shows what a great amount of work he takes upon himself to perform. He lives in the hospital, and now spends most of his time there, and is the only man of note who operates through the summer.

On November 19th I was present at one of Ziemssen's clinics. He presented a case of hernia of the lung, the second case of the kind which has appeared before his clinic since the beginning of the present semester, from congenital deformity in a man aged twenty-three years. On inspiration a part of the lung protruded beneath the skin through an opening in the thoracic wall, due to the absence of part of the third and fourth ribs on the left side. The student who was called upon for the diagnosis showed his originality in conjecture by pronouncing it to be the pectoral muscle. Ziemssen reserves half the time appointed for his clinic, whenever he has a case of interest which has terminated fatally, for the section.

I had the opportunity of seeing an autopsy on the body of a woman, from another department of the hospital, dead from septic poisoning, performed in the pathological institute. The case had been one of placenta prævia, treated by tamponing. During life the patient had suffered from phlegmasia alba dolens of the right leg, and a thrombus was thought to have formed in the crural vein with the possible result of pulmonary embolism. The diagnosis, however, was not supported by the autopsy. In spite of the dissection of the veins the section occupied only forty minutes. The brain was not removed at that time. The bladder, vagina, uterus, and rectum were removed together, and examined separately.

The section-room was a small amphitheatre furnished with stalls instead of benches, in steep tiers, so that the table was in full view of all in the room. Near the lower end of the table and upon it rested a stand high above the body, on which the organs as they were removed were examined. The assistant stood at hand with running water, from a hose, which he played over the organs. As soon as each organ was examined it was transferred to a pair of scales at the foot of the table, weighed by the assistant, and then laid aside, so that the table was always free. It is interesting to observe the difference between the German methods and our own, especially in the handling of gross pathological material. Their convenience of appliances, their thoroughness and skill are striking to the Americans who are familiar with the usual methods pursued at home.

AN EXPLANATORY NOTE.

To the Editor of THE MEDICAL NEWS,

SIR: We did not intend to take notice of the editorial entitled "A Wolf in Sheep's Clothing," on page 380, or the item headed "An Impudent Note," on page 389 of THE MEDICAL NEWS, dated October 5, 1889; but upon the urgent requests of some our professional friends we venture to say a few words to you in our defence.

We are glad to be able to say that many medical men, upon reading the above-mentioned editorial and news item, have assured us of their disbelief of the motives attributed to us in connection with the circular letters referred to. Others with whom we have had no opportunity to communicate have, after our real motives were shown them, agreed with us that our management of the advertising would result in increased business both for ourselves and the ophthalmologist as well. With many of your readers we are, of course, unable to communicate, excepting through the columns of your journal; and, while we think the treatment we have received is rather harsh, we also are sure that you will afford us an opportunity to correct any erroneous impressions which may have been formed.

There are, as you certainly know, a large proportion of the public who *will not* go to an ophthalmologist, but insist upon visiting an optician. Nothing that we can do will prevent such people following their inclinations in this particular. Now, we desire to induce such people to come to our store, and by our treatment of them let them see for themselves that it is for their best good to consult an ophthalmologist. To do this, should we refuse to fit them, or so imperfectly do so that they will have good reason to go to some other optician? Certainly not! Our plan is, by advertising to give them what they are seeking, to induce them to come to us, and when they do come, show them their needs so plainly as to make a visit to a physician as near a certainty as possible. To do this, we must not defeat our purpose by refusing to fit them, and thus send them to some optician who will endeavor to furnish them with spherical, cylindrical, prismatic, or what not, in the way of glasses; but we give them the spherical lens which will best suit their eyes, and at the same time give them the names of one or more of the reputable ophthalmologists in the city or vicinity (we refer indiscriminately to all such men with whom we are acquainted), at the same time informing them that while the glasses furnished cannot hurt them, and will no doubt give partially the assistance they require, yet they will obtain more accurate results

if they have a careful examination made by the physician recommended. It must be borne in mind that we do not fit cylindrical or prismatic lenses, except upon a doctor's prescription furnished outside of our store.

By the above-described course we think it will be evident to you that we have, first, sold that person a pair of glasses, thus making him our customer and in a measure holding his trade in the future; second, we have indicated to him the fact that he can obtain more perfect results than we can give him; third, we have called his attention, in a perfectly proper and business-like way, to the advisability of obtaining medical services, but still leaving the matter entirely in his own hands whether he shall avail himself of such services or not.

Our house is the oldest and largest of its character in the United States, and we flatter ourselves no other can have a higher standard for knowledge and system in conducting its business, nor none a more conscientious desire to avoid small practices and mean subterfuges to attract business.

Our desire is, and always has been, to go forward hand in hand with the medical profession, in advancing their interests, improving their apparatus, at the same time lessening its cost to them; and all that we ask in return is their patronage and good will.

Yours sincerely, James W. Queen & Co.

924 Chestnut Street.

NEWS ITEMS.

Private Asylums for the Insane in New York.—The following resolution was recently passed by the New York State Commission in Lunacy:

"*Resolved*, That hereafter no license for the establishment and keeping of an asylum for the care, custody, or treatment of the insane or persons of unsound mind, for compensation or hire, shall be granted except to a duly qualified medical practitioner of recognized professional skill and standing, who is a graduate of a legally incorporated medical college, and has had actual experience in the care and treatment of the insane."

Cholera advancing toward Europe.—According to the *Lancet*, there is good reason for believing that the epidemic of cholera which has for so many months hung about the Tigris and Euphrates valleys, and the interior of Mesopotamia, has made considerable inroads into Persia. News of its having crossed the western boundary of that empire has been received from time to time, but it is now announced at the Faculty of Medicine of Paris that there has been an alarming increase of the disease in Central Persia and on the Turco-Persian frontier; and that the people are fleeing northward. Those who can afford the journey are endeavoring to reach Russian ports on the Caspian, and remembering that this is the route into Europe which cholera has so often taken before, the announcement must be regarded as one of no little gravity.

Resolutions upon the Death of Dr. James H. Hutchinson.—At a special meeting of the medical and surgical staffs of the various departments of the Pennsylvania Hospital, held January 8, 1890, the following resolutions were adopted:

"*Resolved*, That by the sudden death of Dr. James H. Hutchinson we have been deprived of a valued and beloved associate, while the Hospital has lost an able and faithful officer, the medical profession a distinguished ornament, and the community one of its best citizens.

"*Resolved*, That we hereby place upon record our high estimate of the character of our departed colleague, who, during the many years of his professional life among us, commanded our respect by his ability and sterling integrity, while his genial and kindly disposition won for him our warm friendship; he has left behind him a spotless reputation, and a memory which will be always dear to those who were privileged to know him.

"John H. Packard, M.D.,
"Secretary of Staff."

Obituary.—Dr. Charles Macmillan, Medical Referee of the Pension Bureau, a distinguished surgeon on the staff of General U. S. Grant during the War of the Rebellion, died at his home in Washington, D. C., on January 8th. Dr. Macmillan was born in Livingston County, New York, and adopted the profession of his father, who was a well-known physician. He left his private practice, and joined the volunteer corps of the United States Army as a surgeon at the first call for troops at the beginning of the Rebellion, and served throughout the War with honor. At the close of the War he returned to private life, but was recalled to the public service when General Grant was elected to the presidency, and was made American Consul at Rome. He remained at this post until after the election of President Hayes, when he began the practice of medicine in Washington.

———Dr. Anton von Troeltsch, of Wurtzburg, an otologist of world-wide reputation, died on January 11th. His text-book on aural surgery went through several editions in Germany, and there have been at least three editions of its English translation.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING JANUARY 18, 1890.

Scott, H. B., *Passed Assistant Surgeon.*—Granted extension of sick leave for one year from February 1.

Woods, George W., *Medical Inspector.*—Detached from Mare Island Navy Yard, and ordered to the U.S.S. "Charleston."

Doerr, Ezra, *Surgeon.*—Detached from the U. S. S. "Nipsic," and ordered home.

Dickinson, Dwight, *Surgeon.*—Detached from Mare Island Hospital and ordered to the Navy Yard.

Baldwin, L. B., *Passed Assistant Surgeon.*—Ordered to the U. S. S. "Michigan."

Cordeiro, F. J. B., *Passed Assistant Surgeon.*—Detached from the Mare Island Hospital, and ordered to the U. S. S. "Nipsic."

Edgar, J. M., *Passed Assistant Surgeon.*—Detached from the U. S. S. "Michigan," and ordered to the Naval Hospital, Mare Island, California.

Bailey, T. B., *Assistant Surgeon.*—Detached from the U.S.S. "Dale," and ordered to the U. S. S. "St. Louis."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 14 TO JANUARY 20, 1890.

By direction of the Secretary of War, the leave of absence granted Major Calvin De Witt, *Surgeon*, in *S. O. 146*, December 21, 1889, Department of Dakota, is extended to include February 20, 1890.—Par. 5, *S. O.* 12, *Headquarters of the Army, A. G. O.*, January 15, 1890.

ORIGINAL LECTURES.

THERAPEUTICS OF DIGITALIS.

A Lecture,
delivered at the University of Pennsylvania,

BY H. C. WOOD, M.D., LL.D.,
PROFESSOR OF THERAPEUTICS.

GENTLEMEN: In our last lecture we considered the physiological action of the drug digitalis, and found that its chief action is upon the heart and the arterial system; that it stimulates the pneumogastric nerve, and thereby slows the heart; that it also acts directly upon the heart-muscle and strengthens it; and that it further affects the vascular system so as to produce contraction of the small vessels, partly by an action on the vaso-motor centre and partly by an influence directly upon the coats of the vessels themselves.

Allow me, as is common with lecturers on heart disease, to use the term "heart dilatation" to express the condition of the heart in which its cavities are not equally enlarged but the cells are weakened and the term "cardiac hypertrophy" to express that condition in which there is or is not dilatation with an increase of the cavity of the heart and an increase in the power of the heart wall.

That condition, then, of heart disease which is especially met by digitalis is endocarditis; and you will find the greatest triumphs achieved by the drug in those cases in which there is simple dilatation or weakening of the cardiac walls. Even when the weakness of the wall is due to a fatty or other degeneration, digitalis is often of the greatest service. There is a type of disease that was commonly seen during the war among soldiers, which is closely related to heart dilatation, viz., the so-called irritable heart. This condition of the heart is seen at times in civil practice. The symptoms which it produces consist of excessive cardiac palpitation upon slightest exertion; there is continual excitability of the heart, followed, usually, but not immediately accompanied, by organic change. The organic change sometimes takes the form of hypertrophy; more frequently the "irritable heart" ends in a weak heart.

Digitalis is especially useful in most cases of disease of the heart, not only by virtue of its strengthening power, but by virtue of the peculiar action which it exerts upon the pneumogastric nerve. The so-called irritable heart of the soldier is undoubtedly the outcome of pneumogastric depression, and is most effectively met by rest and the use of digitalis.

The opposite condition to dilatation, viz., hypertrophy, is, as you can well see, aggravated rather than relieved by digitalis. In hypertrophy there is excessive muscular development, and this excessive output of muscular force is increased by the use of digitalis. Here you require remedies to depress cardiac action. The number of cases of heart disease, however, in which the walls of the heart alone are affected is comparatively few. In the great mass of cases we have valvular lesions, causing cardiac muscular lesions. It is especially in the treatment of cardiac valvular lesions that digitalis is of service.

Some persons entertain the idea that to have heart disease is to be immediately disabled. I was taught, however, by my experience with a patient very early in my practice, that cardiac disease may exist for years, the patient leading a happy and useful life. I allude to an old lady, who finally died under my care, who had been a nurse in the family of General Washington, who had been a patient of Rush, whose life had been rooted in the past century. Through all the decades, as far as I could trace her history back, she had had a severe organic disease of the mitral valves, and yet she lived to an age of somewhere in the eighties.

We are now brought directly face to face with a study of the method in which nature brings about a cure or relief in cases of cardiac valvular lesions. When the masses of coagula have altered, changed, and distorted the valve, nature has no power of repairing that valve. We have no power, medical or natural, of adding to the valve that is partially destroyed or of tearing down the valve that has been added to by the disease. All that nature can do is to increase the power of the structure. I do not know how many of you have done as I was accustomed to do in my youth when, early in the morning, I went out into the yard where the cattle were to be watered, and having an old, leaky pump, whose valves were forever dropping water, I labored to get the water up. It was necessary to make the strokes vigorously, and by and by, through the power of my arm, I overcame the loss of power in the valve. This is exactly what nature seeks to do in heart disease, viz., to increase the power of the cardiac structure until it makes up the loss from the destruction of valvular tissue. If the heart becomes so balanced that there is sufficient increase in the muscle to atone for the injury to the valve, then life goes on as usual The difficulty, the danger, the death that is brought about finally, in most cases results from the fact that nature fails or is unable to bring about an exact compensatory hypertrophy; there is too little or too much of power in the muscle to atone exactly for the inequality in the valve; and thus, little by little, changes follow, because these two antagonistic forces are uneven. The object, therefore, in convalescence from endocarditis in every new case of heart disease is, by nursing, by rest, by proper feeding, by the aid of proper medicaments, if possible, to bring about an exact compensatory hypertrophy. And, therefore, practically, your effort is to build up heart structure; to add to, not to take away from, power. We use digitalis during the convalescence from endocarditis, to aid in bringing up and forming this compensatory hypertrophy. How it does this I shall show you a little more in detail when we come to study the therapeutics of digitalis.

The old valvular lesion is one, after all, which most

frequently claims the attention of the physician. In the treatment of the valvular lesion of the heart, the first thing to be done is to make your therapeutic application. The scientific diagnosis in regard to valvular heart lesion is important, but it is only important in aiding you to reach a conclusion in the therapeutic action. If I had heart disease, I would not care at all whether the physician was able to say which valve was or was not affected, provided only he was able to answer this question, Is the hypertrophy in that part compensatory, is it too little or is it too much—what, in other words, is the relation in the heart that is before us between the outcome of the valve, the output, and the force which is to meet that output?

You will remember that we have two kinds of hypertrophy in heart disease. We have what you may call absolute hypertrophy, a mere absolute gain of strength, when the heart is two or three times as strong as it ought to be. But that heart which is absolutely hypertrophied may be relatively dilated or weakened.

Suppose, for instance, we have a heart the power of which is "100" while the power in the muscle is "100". That heart is a normal, healthy heart, and the blood flows in regular cadence. Valvular disease comes, and this "100" increases to "500", because the leak in the valves has required five times the amount of force to make the blood flow regularly. This "100" may rise to "300", and the heart be three times as strong as it was when normal or before the disease came; and yet the power is not equal to the demand; and you have, under these circumstances, an absolute hypertrophy but a relative dilatation. You have a heart three times as strong as normal, but a heart that is fatally weakened in regard to the amount of work necessary for the comfort and the life of the individual. The therapeutic diagnosis to be made in any individual case, the important practical diagnosis, is not whether there is absolute hypertrophy, but whether there is relative hypertrophy or relative dilatation—whether the increase in the power of the heart is or is not proportionate with the increase of the work required. Now, how do we ascertain that? You are aided a little by valvular lesion, but, after all, not materially. When the heart fails you find that the venous system is full, that there is a tendency to dropsy, that the right side of the heart is distended; that the aortic system, in other words, is comparatively empty and the venous system comparatively full. When you find this condition, you know almost to a certainty that you have a case of relative dilatation or weakness of the heart. Hence in almost all cardiac dropsies digitalis is indicated.

Let us take the individual lesions of the heart, for a moment, and consider how digitalis acts. Take a simple case for our purpose, that of mitral regurgitation. There you have a heart in which, when the ventricle contracts, the blood, instead of rushing out into the aorta, is some of it forced back into the auricle; and thus the aorta gets only a portion of what is its due. The aorta being empty, the whole arterial system is empty, and everywhere, from all portions of the body, the cry comes for more blood. The heart attempts to respond; and by and by, from perpetual irritation, the heart becomes as it were angry; it loses the power of self-control. Now, instead of the 60 or 70 strong beats a minute that you ought to have, you have a heart that is beating 120 or 130 times a minute, it may be—at all events far above the normal rate, and each beat is ineffectual. For a heart-beat to be effectual it must have a ventricle full of blood and be able to contract upon something and to throw that something into the aorta. Your little, continual, impatient beats mean continual emptiness all over the arterial system, continual cries for more blood, continual loss of potency; and so we have a weakened, cold circulation everywhere, and a circulation that grows worse and worse.

How does digitalis bring relief? It is not a rag with which you can stuff the lesion down. It is not a lever that you can put on the mitral valve. Digitalis does this: First, by virtue of its action on the inhibitory nerve and, to some extent, by virtue of its action on the heart muscle it quiets the heart. It makes the heart deaf to the impulses coming to it from all portions of the system; and, instead of 120 or 130 beats a minute, you have a pulse of 60 or 70 a minute; and during the long pauses the ventricle fills itself with blood. Now when it comes to contract, it finds that it has within its embrace a great mass of blood which can be squeezed out through the aorta. So that, in the first place, you have produced quiet in the heart, you have a heart filled with blood that may be expelled; and when the contraction comes it is a great, powerful contraction, in which has been gathered up a force that previously was wasted in many different contractions. More than this: you know very well that when you used the pump in order to atone for the leaking valve, you had to make the strokes very powerfully and quickly; and you know very well that there is friction in the small opening, which is greatly increased by the power behind the flood forcing the flood through. The aorta is wide and open and ready for blood; the little opening in the mitral valve is choked up with excrescences, is irregular and small: so that, when the powerful contraction comes, there is an immense increase of friction in the mitral valve with but little increase in the aorta and the blood chokes itself up, as it were, so that but very little blood gets up into the venous system.

You see, under these circumstances, how digitalis increases not only the amount of blood that goes out of the aorta, but increases the proportionate percentage of blood that goes out as compared with that which goes backward. I have hardly time to-day—in fact, I have not time in the hour allotted to me—to take up the individual cardiac valvular lesions and trace out the way in which digitalis does good in each individual lesion.

There is one class of valvular diseases in which, common opinion says, digitalis does harm, and that is, in aortic disease. The use of digitalis in diseases of the aortic valve is governed by the same laws which govern its use in diseases of the mitral valve. Whenever in diseases of the aortic valve the heart is weak, you use digitalis precisely as you use it in diseases of the mitral valve. But it so happens that, in cases of aortic disease, excessive hypertrophy is common, while it is very rare in cases of mirtal disease. So that if you take at random a thousand cases of cardiac disease, you will find that digitalis suits a larger percentage of mitral disease cases than of cases of aortic disease. This is not because there is any difference in the application of the

remedy or in the rules governing it, but simply because aortic disease more frequently gives rise to excessive hypertrophy than does mitral disease.

Gentlemen, very extraordinary permanent results are sometimes seen in heart disease from the use of digitalis. I have seen a case, for instance, in which a laboring man, unable to work, whose condition in his cardiac indications was apparently hopeless, become able to work in a few days and go for some months without taking more digitalis. It would seem, therefore, in view of its effects in heart disease, that the drug does more than simply stimulate the heart, and that it ought to be classed as a cardiac tonic and food rather than a cardiac stimulant. It is very easy to see how digitalis, under these circumstances, does good. You know that when the aorta is filled and distended with blood coming from a powerful contraction, the circulation in the cardiac walls is especially affected. Now you have a heart, we will say, that is overworked from valvular disease, a heart that is unable to throw sufficient blood to feed the general system, a heart that is starving itself, because failure in circulation is felt in the heart wall more severely, even than in the periphery of the body. You have, therefore, a heart that is overworked and underfed; and you know full well that when you are overworked and under-fed, you undergo rapid exhaustion, and have need of change. I have no doubt that one cause of heart failure and valvular lesions is underfeeding of the heart wall with blood. Now, you restore that heart to a normal action temporarily by the use of digitalis, by the stimulation of digitalis, if you please; and, consequently, when the current rushes out through the aorta, there is a great mass of it to go into the veins and arteries to feed the walls. When the heart contracts with a spasm, it contracts with such force that it empties out all the juices from the muscles and makes a clear, open space for the blood to flow in and to feed the heart. And so the heart ceases from its overwork, has a rest from its excessive labor, and is also fed more liberally than it was before. The digitalis, in these cases, does good temporarily by restoring the balance of the circulation; permanently, by bringing rest and food to the heart itself.

But I believe myself that digitalis goes beyond this. The experiments of Gaskill have shown that the pneumogastric nerve is a trophic nerve of the heart; that during the period of inhibition there is not only rest from functional activity, but there is activity in structural change; that during the systole of the heart, in other words, the heart puts forth energy and destroys its own structure; that during diastole of the heart the heart not only rests from functional activity, but is engaged in building up its own structure. Systole is destructive to the heart; diastole is constructive to the heart. Now, therefore, when you have a long period of diastole, you have an increase in the structural activities of the heart. And so there comes to the heart not only cessation from worry, not only over-feeding instead of under-feeding, but also an intensely stimulated structural activity. Under these circumstances, is it wonderful that the effect of digitalis in cardiac disease is so often permanent?

You can see how, properly used, digitalis is a remedy of great value in the treatment of the formative phase, so to speak, of heart disease and in convalescence. It regulates the heart's action, it causes the muscle to be well-fed, and it stimulates activity in that muscle. Its use, therefore, is of immense importance in building up activity in the heart structure, if there is any hope for the patient.

Let me now say a few words in regard to the use of digitalis in old cases of heart disease. In the cases of heart disease of which I have been speaking and which are not very severe, especially in the early stages, I would recommend ten drops of tincture of digitalis, three times a day. But there is a class of cases in which most wonderful therapeutic results have been attained by the inordinate use, so to speak, of digitalis. I remember being called upon by an old German doctor, who asked me to take care of a lady patient during his absence. The lady lived in Cherry Street, opposite the St. Paul burying-ground. When I visited her she was sitting at a window, leaning forward, and in that horrible agony of a protracted struggle for breath which attends the last stages of heart disease. After a few formal words of introduction to the patient, I asked the physician, "Have you given digitalis?" He replied that he had. I then inquired, "Have you given massive doses?" He answered, "No." I asked, "Are you and is she willing to take the risk?" He replied substantially that it would be better for the patient to be in the graveyard, to which he pointed, than to continue to suffer as she was then suffering. The lady assented to my proposition, and I began to administer to her doses of half a drachm of tincture of digitalis, three times a day. When the doctor came back, three weeks later, the lady herself came down to the door to greet him. In another case a banker from the West, who was at one of our hotels, had become suddenly worse with an aggravation of his cardiac disease, and had been at his hotel, four or five weeks, under the care of a homœopathist. I found that man sitting up, but with the most absolute characteristics of the disease that could be conceived of. He would cease breathing for a minute or so, and then, when apparently about to die, would suddenly rise up and spasmodically catch his breath. After a long pause he would again spring up, gasping for breath. I put that man on enormous doses of digitalis, and in two weeks he was able to go to his home in St. Louis.

Now, gentlemen, remember that each of those cases was an advanced stage of cardiac disease, in which life was a misery and death a thing to be hoped for. By the use of digitalis the patients were restored, for the time being, to the power of active life. But mark you the final result. The banker, one day, fell dead across the threshold of his bank; the old woman, early one morning, fell dead upon the stall of the market where she was making her purchase.

Now, those people were not killed by digitalis. Digitalis had not produced in those people a sudden cardiac arrest. But what digitalis had done to those hearts was this: it had steadied them, stimulated them, built them up, brought them into that condition in which they were able to utilize the last grain of force that was remaining in the storehouse of their power, and to make use of that force until, at last, it was expended When the last grain was gone, the heart stopped. Life had been prolonged, life had been made comfortable; death, when it came, came as the lightning shock.

Therefore, whenever you have these old cases of heart disease, make up your minds that you are justified in using these enormous doses of digitalis; but remember what the probable end will be, and take care that you warn the patient and warn the friends of the patient, so that they may know what is to be expected.

There is a condition of the arterial system allied with or often coexistent with the aortic disease in which, not many years since, surgeons used digitalis. I refer to aneurism. But you see at once that digitalis is a most dangerous remedy in the treatment of aneurism. The only reason why the surgeon has failed to do harm in the use of digitalis in aneurism is that he gave it in such small doses that the drug had no effect. You take an aortic arch partially torn asunder, weakened by disease and ready to burst, and you send through that aortic arch not the little, feeble stream of failing heart-power, but the great, mighty current produced under digitalis. This force is propelled forward, and there is also a lateral force exerted of necessity, and especially is that lateral force exerted when there comes the reflex wave driven back by heart-pressure on the aortic valve, and with such force as to rebound. There is great danger that, under these circumstances, the wall will give way. The reason that that has not oftener happened is because the digitalis was given in such small doses that it probably had no effect. This is not mere theory. Some years ago, when I was a physician in Blockley Hospital, there came a man into a ward in a condition of collapse, who had been picked up in the street in a dying condition, with a temperature far below normal and a pulse which was not perceptible. I said, "I do not know what is the matter with this man; give him digitalis and other stimulants." Digitalis was administered, and I saw the man two days afterward. As I stood by his bedside I felt the great, huge digitalis wave coming up under my finger, and I said, "Give this man no more digitalis," as his pulse showed unquestionably the effect of it. Suddenly the man, with a struggle, braced himself in the bed and threw himself forward. A great rush of blood came out of his mouth and he fell back—he was dead. I said at once to the resident physician, "Do you know what we have done? That man had internal aneurism, and we have burst it with digitalis." There was the aortic artery rent as though with human fingers; the digitalis had seized upon it and torn it asunder.

In the hurry of preparation I have overlooked one or two points which I should have mentioned, and I will now give you these a little out of order, viz., as to the failure of digitalis to do good in certain cases of heart disease. First, let me say one other word in regard to the therapeutic diagnosis. I have told you how to make it. If in some cases, when exercising the utmost care, you are doubtful whether a heart is weak, whether it is dilated or whether it is strong, then you make a therapeutic test. If digitalis renders that heart more irritable and increases the distress of the patient, you know that the heart is hypertrophied. This applies also to some cases of valvular lesions, where you suspect that you have made a mistake in your therapeutic diagnosis and that the case is really one in which there is relative hypertrophy, but not, as you had thought, relative dilatation. But there are cases frequently met with in which the use of digitalis seems to be indicated, and in which it increases greatly the distress of the patient, but in which you are sure there is relative dilatation or weakness of the heart of the patient. These are cases of mitral insufficiency. Where you have a miserable cardiac dropsy and a failure everywhere in arterial circulation, give digitalis and observe the results you get from it.

In other words, digitalis seems to stimulate the ventricles more powerfully than it stimulates the auricles. Then, again, remember that the ventricle is always overpowerful when compared with the auricle in the heart. When you have a ventricular beat, you have a strong contraction, throwing the blood back upon the auricle. If, under these circumstances, you have an auricle which is very weak, and you give digitalis, the ventricle becomes excessively powerful; and when it drives the blood back upon that auricle, it drives it back with such power that the auricle is not able to react, and, instead of reacting against the ventricle, the auricle yields and the valve stretches and becomes weak. Then comes the cardiac result, which is not the outcome of a ventricular failure, but the outcome of a ventricular strain. It is under these circumstances that you have such a period of ventricular strain that the auricle gives way and you have distress.

One word in regard to the use of digitalis in cases of cardiac dropsy. You cannot rely upon digitalis as a direct stimulant to the urinary or secretive organs. When you have failure of urinary secretion, it is because there is failure of circulation in the kidneys. Under these circumstances, of course, by regulating the blood circulation the digitalis will increase the urinary secretions. The great value which it has in cardiac dropsy is by restoring everywhere the balance of the circulation.

A CASE OF GASTRO-ENTEROSTOMY AFTER SENN'S METHOD FOR CANCEROUS OBSTRUCTION OF THE PYLORUS.[1]

By M. STAMM, M.D.,
OF FREMONT, OHIO.

Mrs. M., aged sixty-three years, had felt some pain in the left epigastric region since the beginning of March, 1889. On July 6th, she first came to my office and told me that for the past three weeks she had noticed a hard tumor in the region of her stomach, complaining at the same time of loss of appetite, acid eructations, loss of flesh and strength. I was struck by her appearance, as in February when I had last seen her she was a picture of perfect health and weighed about 197 pounds. Now she apparently did not weigh more than 140 pounds, and had a decided cachectic appearance. On examination, a solid nodular tumor was discovered in the epigastric region midway between the ensiform cartilage and umbilicus. The area of dulness was about the size of two hands; tumor did not appear to be movable. On July 9th, I examined her again

[1] Read before the Northwestern Ohio Medical Association at Toledo, Ohio, December 12, 1889.

with Dr. Gessner, of Fremont. After inflation of the stomach with carbonic acid gas, the tympanitic sound reached to about two inches below the umbilicus; the tumor was not displaced, the nodules seemed to separate slightly, some taking a course along the lesser curvature. Dulness over the liver reached about two inches below the ribs. After having emptied the stomach of gas with the tube, I injected nearly three quarts of warm water into the bowels, following Naunyn's advice. The tumor disappeared from touch, but the dulness remained the same. Consequently we arrived at the diagnosis of carcinoma of the pylorus, including the lesser curvature. Patient insisted upon knowing her real condition, which we could not very well hide from her, as she had already independently formed similar conclusions. She then said she knew what the result would be, as there was no hope for a cure. As a mere consolation, we told her that in recent years surgery had taken hold of such cases and that a few had lived for several years in comfort after operation. She would not hear of an operation, especially as I told her that it was generally very dangerous and could not be lightly advised by a conscientious physician—in fact, should only be undertaken at the urgent request of the patient. At my subsequent visits she repeatedly and spontaneously referred to an operation as a thing she would never consent to, and in return I always told her that I had no desire to advise such an interference, knowing very well that on account of the immobility of the tumor a resection of the pylorus was out of question. Not a little surprised was I, therefore, when, in August, she sent me word that she was now determined to undergo an operation. In vain I explained to her and her husband the impossibility of a complete removal of the growth, that any operation would at best only give her temporary relief, and probably that but for a short time. But as symptoms of pyloric obstruction had set in, she was bound to get relief at any cost.

August 22d was decided upon for the operation. I therefore washed out her stomach on August 20th, and again on the evening previous to the operation. At her request, she was allowed to take half a cupful of black coffee about 4 o'clock in the morning, before the operation, with the intention of washing out her stomach again about six hours later. She, however, when that time came, objected so strenuously to such a step, that she was ready to give up the operation rather than submit to another lavage.

My intention was to perform either gastro-enterostomy or Bernay's operation, which latter consists in gastrstromy and scooping out the cancerous mass. Bernay's two cases which he reported in the *Annals of Surgery*, December, 1887, certainly encourage such a procedure in suitable cases, but, as will be seen, my case presented too extensive an infiltration to admit of any such measures.

The incision was made in the median line, where the stomach presented itself readily. The cancer was located in the lesser curvature, and the pylorus formed one rigid mass, being adherent to liver and pancreas. A number of nodules were also found in the liver and some in the anterior wall of the stomach. I introduced my right hand into the abdominal cavity down to the pelvis and caught up what I thought was the upper part of the ileum. Nothnagel's test, which consists in placing a grain of salt on the serous surface of the bowels to elicit ascending peristalsis, was a complete failure in my case. Consequently I followed the coil of intestine, which I held in my fingers, up for some distance until I felt the mesentery become shorter and selected the corresponding part for the opening. As a ligature for the bowels, to prevent any escape of their contents, I took two small rubber bands, passed them with the eyed end of a probe through the mesentery about four inches apart, and, after having pressed out the contents of the intervening coil, I fastened the bands with Pean's hæmostatic forceps. An incision about one and a quarter inches in length was then made upon the convex surface of the intestine, and the decalcified bone plate introduced. After having transfixed the bowel by both lateral sutures, I handed it over to one assistant, and made an incision into the stomach about the middle of the greater curvature and one inch above the insertion of the omentum. The black coffee which the patient took about seven hours before was found in undiminished quantity in the stomach and caused some delay in the operation, as it had to be emptied by means of the syringe. For the stomach I used an undecalcified bone plate, as Senn has recommended. The threads were then tied and the plates adjusted. As an uneasy feeling crept over me at the thought of returning the sutured parts into the abdominal cavity, I introduced about fifteen Lembert sutures for the purpose of reinforcement. A second case, no doubt, will make me less apprehensive, so that I may restrict myself only to a few Lembert sutures, but I think every novice in such a matter will undoubtedly share the feelings I had at the time.

Patient rallied well from the operation; not the slightest sign of collapse was shown, although she regurgitated a few mouthfuls of black coffee about four times during the first twenty-four hours. The next morning I succeeded in getting her consent to have her stomach washed out again, which was done without retching, as a few minutes before I had brushed out her pharynx with a ten per cent. solution of cocaine. This gave her complete relief, and at each of my subsequent visits she expressed herself as feeling surprisingly well. Her temperature never exceeded 100°. On the third day her bowels moved slightly, after an enema. Enemata of brandy and peptonized milk, also the yolk of an egg, were given to her the first three days; afterward she took food by the mouth. Her bowels moved every morning for five weeks. Her condition was really very satisfactory for four weeks, although her tumor kept on growing very rapidly. At the end of four weeks she began to vomit occasionally, mostly mucus, but still she took nourishment up to the end of the fifth week. After that time she lived principally on wine and water. On October 4th she died from progressive marasmus, without the least suffering or distress.

Post-mortem, on October 5th, revealed stomach,

liver and pancreas almost totally degenerated. The anastomosed parts were slightly adherent to the abdominal incision; the artificial opening would admit the index finger very readily. The portion of the bowel which I had selected for anastomosis was the upper part of the ileum. The bone plate was found lying loose in the stomach, the decalcified plate in the bowels was no doubt absorbed, as it could not be found, and never had passed with the stools. Gall bladder contained an immense gall-stone, which, however, had not caused any symptoms.

Now we may naturally ask the question, Is gastro-enterostomy a justifiable operation for cancer of the pylorus? Is it worth while to undertake an operation of such magnitude in a case where a cure is absolutely out of the question? I might premise in saying that, in such an instance, the opinion of the highest medical authority is of little weight unless supported by clinical facts. In order to decide this question, we must first look at the rate of mortality immediately connected with the operation. Von Hacker's report from the Vienna clinic, in 1886, was certainly not very encouraging. Of 8 cases of gastro-enterostomy, after Woelfler's method, 5 died promptly, and the 3 cases which recovered enjoyed only a short improvement. But the cause of this high mortality could be easily explained by the fact that in several cases an attempt at total resection of the pylorus had preceded the gastro-enterostomy, and only when they found the adhesions too extensive did they resort to Woelfler's method. Satzmann also published a table of 23 cases of gastro-enterostomy,[1] 18 cases for cancer and 5 cases for cicatricial constriction of the pylorus. Of these 18 cases of cancer 12 died, while those which recovered lived between one and four months. It is no surprise, therefore, that these two authors did not take kindly to the operation. A much more favorable report is published by Rockwitz,[2] from the Strassburg Clinic. One case was operated upon by Fischer, on May 13, 1882. The woman, about thirty-one years old, gained seven pounds during the first four weeks, was able to do some light housework, and died one year and two months after operation. He further reports seven cases from Luecke's clinic. Of this number, 1 died about eighteen days after the operation from inanition and pneumonia. In this case the mesentery of the ileum at the seat of anastomosis produced a partial constriction of the transverse colon. The other cases lived from three months to nearly one year, greatly relieved of the distressing symptoms. Dr. Angerer, of Munich, reported 6 cases of gastro-enterostomy at the Congress of German Surgeons last spring. One case lived for months, and was able to work as a mason, though he frequently suffered from colicky pains, 2 cases died in a few weeks, and 3 a few days after the operation. Lauenstein, of Hamburg, at the same time added 9 cases, of which he lost 2 in immediate consequence of the operation, the remainder living for a longer time free from all unpleasant symptoms. Dr. Ransohoff, of Cincinnati, was kind enough to send me an extract from the London *Lancet*, vol. ii., 1889, p. 986, containing the report of a case operated on by Mr. Herbert Page, and read at the meeting of the Royal Medical and Chirurgical Society, May 14, 1889. The patient, a man aged forty-eight years, had a malignant pyloric obstruction for several months, and was operated on in St. Mary's Hospital in December, 1887, after Woelfler's method. He was much relieved by the operation, and lived for seventy-two days in comparative comfort, but did not gain in weight, which he thinks was due to the fact revealed at the autopsy that the lower portion of the ilium was used for the anastomosis. He appended a table of 38 cases furnished by different operators, 2 of which were subjected to both pylorectomy and gastro-enterostomy at the same time. Of the 36 cases of gastro-enterostomy alone, 15 were fatal directly or indirectly as the result of the operation. But he noticed a steady decline in the rate of mortality. In the first 18 cases there were 10 deaths, while in the second 18 there were 5 only. Czerny reports 11 cases from his own clinic, 5 operations after Woelfler's, and 6 after von Hacker's method, with 7 deaths. The first case in this country was the one of Ransohoff, operated on in 1884, after Woelfler's method. Patient died eight hours after operation from collapse. Another case operated on about two years ago by Lange, of New York, died thirty-one days after operation from perforation of the posterior wall of the stomach at the side of the carcinomatous ulcer. Meyer, of New York, reported a case[1] where he followed Woelfler's method with continuous catgut suture. Death followed five days after operation from ileus, which Meyer ascribes to the fact that the anastomosed portion was selected too far away from the pylorus.

In my opinion, the cases from the Strassburg clinic, and those where the advice of Rockwitz has been followed, are alone of practical value in fixing the rate of mortality for operations after Woelfler's method. Rockwitz has pointed out the necessity of confining the operation simply to those cases which are not too much reduced in strength, and in cases where the condition leaves one undecided whether to make a radical excision or resort to gastro-enterostomy, to cast the die in favor of the latter operation. The secret of Luecke's and Fischer's success undoubtedly centres in that fact. Luecke's operations lasted on an average one hour and a half, and they were generally followed by considerable

[1] Centralblatt f. Chirurgie, No. 33, 1886.

[2] Deutsche Zeitschrift f. Chirurgie, Bd. xxv., Heft 3.

[1] New York Medical Journal, June 22, 1889.

collapse. How much better able must we be now to attain success since that indefatigable investigator and fruitful genius, Dr. Senn, has given us a method so simple and rapid of execution, that collapse and immediate death after the operation will almost reflect upon the skill and good sense of the surgeon. The use of bone plates has made gastro-enterostomy in practice a very safe method. Dr. Senn, in a recent letter to me, reports 7 cases of his own, of which number only 1 died shortly after the operation. This case really represented the most extreme limit of operative venture, as the patient was already at death's door. It was the first case the doctor had operated on, and very probably in the future such cases will be allowed to die a natural death. The rest of the cases lived for several months, free from symptoms of pyloric obstruction. Dr. Ransohoff, in a letter, gave me a history of his case which was operated on last spring after Senn's method. For three weeks everything was in the best condition, but after that time the symptoms returned, and patient died one month after operation. At the necropsy the opening was found too small to substitute the normal pylorus, and the operator ascribes this to the bone plates. He thinks he will use Abbe's catgut rings in the future. So we have 9 cases after Senn's method from three operators, with but 1 death as the immediate result of the operation, and we may assume that in the future the mortality will be reduced to almost *nil*.

The second question, "Is it worth while to undertake an operation of such magnitude in a case where a cure is absolutely out of the question?" is certainly not out of order here. It seems to be a settled fact amongst physicians, that in cases of pyloric obstruction they have hitherto been wellnigh powerless. And, I think, most physicians who have been confronted with such cases, and who have a heart for human suffering, would have been glad to bring relief even at some cost; indeed, I think most patients in this terrible condition will drive their medical attendants to desperate means. Does this operation really give the desired relief? In answer to these questions I can only quote the opinions of those surgeons who have operated. Rockwitz says:

"I have never seen a happier and more grateful set of patients than the class affected with pyloric obstruction as, after a complaint long and full of torture, they see themselves suddenly relieved from pain and other disturbances, and gain renewed vigor and courage to live."

Senn, in his work on intestinal surgery, says:

"These cases have satisfied me that gastro-enterostomy in cases of inoperable carcinomatous stenosis of the stomach is a safe and justifiable operation, and should be more frequently resorted to, as it is the only resource which promises substantial relief, prolongs life, and infuses new hope into a class of patients otherwise doomed to a certain, speedy death."

In his letters addressed to me he seems to be even more confirmed in the advisability to operate. Dr. Ransohoff says:

"In cases of carcinoma where a radical operation (pylorectomy) is not possible, I appreciate gastro-enterostomy very highly. In cases of cicatricial stenosis or round ulcer, I would prefer excision or the pyloro-plastic operations (Heinecke-Mikulicz)."

Mr. Herbert Page's opinion is that gastro-enterostomy is worthy of more attention than it has hitherto had in England. In properly selected cases it appeared to him to be an operation distinctly justifiable, and one to be recommended, for it was capable of bringing relief from the distressing symptoms incidental to pyloric obstruction, and was thereby the means, in all probability, of prolonging life.

If one case justifies me in forming an opinion, I can say that the operation in my case prolonged life probably from three to four weeks, that for nearly five weeks the patient was cheerful, and not even without hopes. From the time of operation up to her death she was free from pain and distress of any kind. Considering the extent of cancerous infiltration, she really did as well as could be expected. Moreover, shortly before the operation, she said her only wish was to live long enough to see her daughter safely through her approaching confinement, and that she would like to see the baby; her wish was gratified in its full measure. I, therefore, am fully in favor of this operation, provided we explain to the family the exact condition, and do not promise more than we can realize.

Another question arises, "Should gastro-enterostomy be performed in every case of carcinoma of the pylorus, or should some cases be reserved for pylorectomy?" I think most surgeons now agree to advise excision of the pylorus only in cases where the tumor is movable and the adhesions can easily be separated; in doubtful cases gastro-enterostomy will prove to be the safest method. In regard to operations for the relief of cicatricial stenosis or round ulcer of the pylorus, we suffer from an *embarras de richesse*. Some surgeons are especially partial to Loreta's operation, others to radical excision, some to Heinecke-Mikulicz's method, others again to gastro-enterostomy. All of them have been tried, some with success and some with failures. I think Loreta's operation may be indicated in cases of tonic contraction of the sphincter, or slight, resistless cicatricial stricture. Excision, in my opinion, should be condemned, as to-day we have safer methods. Kroenlein's case, at least, should serve as a warning.[1] He operated for traumatic

[1] Centralblatt f. Chirurgie, No. 40, 1888.

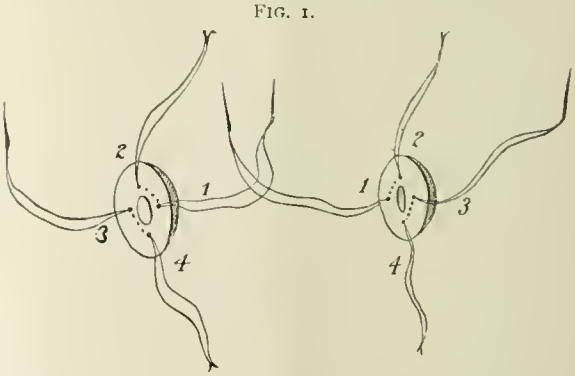
cicatricial stenosis, and found the pylorus adherent to the liver. After making the excision, he found that the transverse cut of the duodenum would only admit a fine probe; it was impossible to extend the resection further down; Kroenlein, therefore, closed the duodenal end with a number of sutures, and inserted the gastric end into a coil of the jejunum. Death followed the next day. As to the plastic operation of Heinecke-Mikulicz, Fritzsche[1] says that Heinecke's operation may at times become so formidable and dangerous that it certainly would be better to replace it by gastro-enterostomy. And, indeed, the latter operation has so far, in the above-mentioned conditions, always been safer, and of more lasting success.

Gastro-enterostomy may also have its use in cancer of the pancreas, where the tumor presses upon the pylorus or duodenum. I saw such a case about six years ago, where the situation of the tumor and the condition of the stools led me to the diagnosis of cancer of the pancreas. The patient suffered terribly for months from obstruction of the pylorus, and, post-mortem, I found that the stenosis was caused by pressure of the pancreatic tumor and by some adhesions. Another reason speaks in favor of operating in cases where a tumor can be felt in the region of the pylorus, causing symptoms of obstruction. I know and have read of cases where a diagnosis of pyloric cancer was made, and a post-mortem revealed a tumor caused by gall-stones. Such cases are certainly very mortifying to the physician, the more so as they can be readily, and with a high degree of safety, relieved by an operation.

A few words might yet be added in regard to the methods we adopt to arrive at a diagnosis of cancer. I think the inflation of the stomach with gas should never be omitted. In my case it demonstrated the immobility of the tumor and the separation of the nodules, outlining at the same time the course which some took along the lesser curvature, thereby making the diagnosis somewhat positive. The injection of water into the bowels is also a very valuable aid in the diagnosis of abdominal tumors, and it assists us especially in determining whether they belong to the stomach, transverse colon, gall-bladder, or omentum. The examination of the stomach as to the presence of acid or its absence may be of service in some cases, but it should not be forgotten that hyperacidity has been observed in a few cases of gastric cancer.

We may now turn to the technique of the operation and to the different points which are of especial value in contributing to the success, immediate or remote, of the operation. Some surgeons think they derive some advantage in regard to the prevention of collapse from the way they use the anæsthetics. They recommend chloroform up to the stage of insensibility, and then to continue the narcosis with ether. I have anæsthetized in that manner for three years—since Kochler recommended it so highly—with increasing satisfaction. I think most operators make the incision in the median line, and from appearances it will hold its place in the future. In regard to the manner of effecting the anastomosis, I think Senn's bone plates will be mostly employed. Ransohoff's dissatisfaction with them can be remedied by making the opening larger and by drilling the suture holes some little distance from the central opening. I must confess I would have a slight hesitancy in using catgut rings for the stomach, for fear they might be too rapidly absorbed. But, again, I do not think it necessary to use undecalcified bone plates for the gastric portion, as in my case it was found nearly intact in the stomach after forty-five days. I have of late prepared my plates from the lower angle of the shoulder-blade of young cattle (a heifer, two years old). They can be easily cut with the knife and are ready for use in half an hour, having kept them for that length of time in absolute alcohol. To prevent them from becoming distorted by warping, they should be compressed between blotting-paper. I have also simplified the manner of passing the threads through the plates. Senn's description on that point has never been clear to me, and I have heard others express the same idea, although all his writings are well appreciated for their terseness and lucidity. I

Fig. 1.

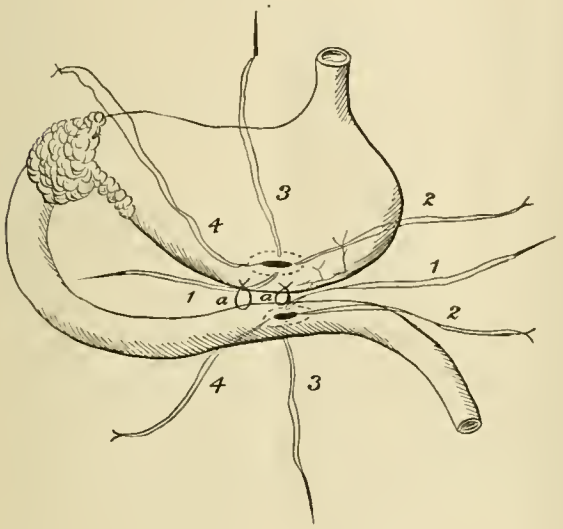


could never see why "the threads should be fastened to the surface of the plate by another thread passing through the perforations in the shape of a loop and fastened at the back." In my case I determined to follow what, in my opinion, seemed to be the simplest way, and which may be easily understood from the accompanying illustration (Fig. 1). For the plate in the stomach the thread is introduced at 2, and comes out at 1—that is, at the right side of the plate. For the bowel it is also introduced at 2, and comes out at 1, but at the left side of the plate. This is done so that the needles, after having trans-

[1] Centralblatt f. Chirurgie, No. 2, 1889.

fixed the bowel, will indicate the threads which should be tied first. After having tied 1, a pull on 2 will bring the plates with the wall of the stomach and bowels together; then tie at 2. Nos. 3 and 4 are then tied in their respective order. To prevent further confusion, it might be well to use black thread for 1 and 2 and white thread for 3 and 4. Before tying the threads, however, it is well to introduce a few Lembert sutures at the lower side, at the point of union of stomach and intestine (Fig. 2, *a a*).

Fig. 2.

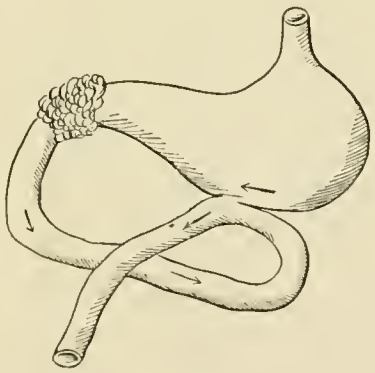


In my case it was neglected, and prolapse of the mucous membrane necessitated two sutures, which were difficult to introduce after the parts were united. It is also well to puncture the serous coats of stomach and bowel overlying the plates, in order to promote rapid adhesion. I further think that a few reinforcement sutures (Lembert's) will put the mind more at ease in regard to perfect union.

The most important question which confronts us is the selection of the proper portion of the intestine for the anastomosis. If you read the report of some operators, it would seem to be an easy matter; others, again, have had considerable trouble in finding it, and they advise simply to go down into the pelvis and take hold of any loop of the smaller intestine that may present itself. But we have a sufficient number of cases on record to make us cautious in selecting the first presenting coil for anastomosis. We have seen in Page's case that nutrition is not carried on properly if we select the lower part of the ileum.

Senn had also some kinking and the formation of a spur in one of his cases which he ascribes to the great length of the intestinal part between the stomach and the new opening, and he recommends to search for the duodenal or upper jejunal portion of the bowels. It should, therefore be our special aim to look for such parts, which, however, is not always such an easy matter as some make it to be. Nothnagel's test, which has been pressed into service very often, proves a failure. Courvoisier's and von Hacker's methods, cutting through the omentum and transverse mesocolon in order to stitch the duodeno-jejunal flexure to the posterior wall of the stomach, will probably not find many imitators, although it took Jesset only thirty minutes to perform it on the dog. The method which at the present commends itself to our special favor is the one of Hahn. With the index finger and thumb of the right hand he searches for that portion of the pancreas which lies over the spinal column, and then takes hold of the coil which directly passes over to the left side. If it does not follow our hand on pulling we have the beginning of the jejunum; passing along this for about twelve to fourteen inches we have the right spot then for anastomosis. Rockwitz thinks it of great importance to promote peristalsis right from the start. In the normal condition he finds it to have a continuous course from the stomach into the bowels, whereas, when we anastomose the parts as it is generally done, the peristalsis of the stomach starts from left to right and that of the bowels from right to left. He therefore advises to attach the bowel in such a way that the efferent coil is to the right and the afferent one to the left. (Fig. 3.) But as

Fig. 3.



far as I could see from my own case and from the cases reported, I think there is no necessity for such a procedure. Should vomiting or symptoms of ileus arise, lavage of the stomach must never be omitted.

REMARKS UPON EMPYEMA.[1]

By Mary Putnam Jacobi, M.D.,
of New York.

I do not propose to enter into an exhaustive statistical discussion in regard to empyema or its treatment. This ground was largely, though not completely, cov-

[1] Read before the New York Academy of Medicine, Section on Pædiatries, November, 1889.

ered in a discussion held at the New York Academy of Medicine, in the winter of 1887, in which several physicians and surgeons took part. I may add that this discussion yielded more positive and useful conclusions in regard to the treatment of empyema than were reached by the discussion of the International Congress at London, in 1881. In six years, a most substantial progress had been effected.

The physiological problems involved in empyema have been discussed theoretically and experimentally, as recently as last September, at the first meeting of the American Pædiatric Society, held in Washington. This discussion was sustained by Drs. O'Dwyer and Northrup, and the President of the Society, all from this city.

It might easily seem, therefore, that nothing remained at present to be said upon the subject. Nevertheless, as various considerations have suggested themselves to me during observations of the case I am about to relate, I take the liberty of laying them before the profession.

A little boy, four years of age, was brought to my office in September, with a history of five weeks' febrile sickness, which had been considered by one physician to be a malarial fever; by another, typhoid. For some time the fever had been of a hectic type, coming on only in the afternoon. On the occasion of the first visit, which was in the morning, the temperature was normal. The child was excessively pale, with a suggestion of œdema in the face, but not elsewhere. The respiration was not accelerated, and cough had been so slight as not to be mentioned by the mother until after I had inquired concerning it. Inspection of the chest, however, at once suggested thoracic trouble, for the anterior portion was markedly arched forward, the arching being equally prominent over the left side and over the sternum, and not much less over the right side. The mother had noticed that the chest was—as she expressed it—swollen. There was some dilatation of the veins over the sternum. On the left side, absolute percussion dulness extended from the second rib over the whole anterior region of the chest and reached the right border of the sternum. Above this zone of absolute dulness, a zone of relative dulness extended to the apex. Posteriorly, dulness extended from the spine of the scapula to the base of the lung. Over the region of absolute dulness, breath sounds were entirely absent. There was no tubular breathing. From the age and fretfulness of the child, it was impossible to obtain whispering pectoriloquy—which is said to be present in serous effusion, absent in empyema, and to constitute a valuable means of diagnosis between them. Above the region of absolute dulness, on the left side, both before and behind, existed tubular breathing; right lung was normal. The apex of the heart pulsated in the epigastrium.

I regret that cytometer measurements of the chest were not made at this time. Nor was it noticed whether the liver was displaced, through compression and compensatory longitudinal enlargement of the right lung.

The assemblage of signs and symptoms just enumerated sufficed to justify an almost positive diagnosis of a purulent effusion in the left pleura, sufficiently abundant to displace the mediastinum considerably to the right side. An exploratory aspiration was deferred until the moment for operation, which was appointed for the afternoon of the same day. At this time the hypodermic needle, inserted painlessly after previous application of ice and salt, withdrew a syringeful of pus.

In saying that anterior mediastinum was displaced, I have used the current expression, but have not used it in regard to the heart, which was found beating in the epigastrium, and which would usually be said to be pushed over. According to the arguments and demonstrations of Douglas Powell,[1] of London, Peyrot,[2] of Paris, and Garland,[3] of Boston, the displacement of the heart in pleural effusion s not due to pressure of the fluid on the diseased side, but to aspiration of the lung on the sound side of the chest. "The mediastinum," observed Dr. Powell in 1869, "is poised by the contending elasticities of the two lungs." The lungs exercise a traction power on the mediastinum, and also on the thoracic walls. The latter have been shown by an experiment of Dr. Salter's, repeated by Dr. Powell, to move outward about $\frac{1}{100}$ of an inch when air was admitted into the pleural cavity after death. This shows that during life, and while the lungs were expanded, they were habitually drawing the thoracic walls inward, by virtue of their elasticity. When the lungs collapsed, by the admission of air into the pleura, this traction ceased, and the thoracic walls moved outward to an extent corresponding to the previous retraction. The same degree of traction must necessarily be exerted on all parts of the pleural cavity, hence upon the mediastinal walls as well as on the thoracic. But as both lungs exercise the same pressure, each, normally, neutralizes the influence of the other, and the heart remains poised or suspended from the attachments of its great vessels, between two equal opposing forces.

If, now, the elastic traction of one lung diminishes, the power of the other lung is proportionately increased, and the mediastinum, with the heart contained in it, is accordingly drawn to that side.

Dr. Powell points out that it is only in this way

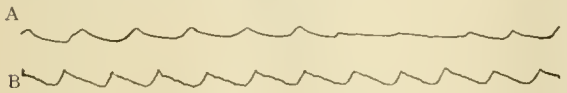
[1] British Medical Journal, 1869.
[2] Archives Gén. de Méd., 1876.
[3] Boston Med. and Surg. Journ., 1878, and monograph.

that we can explain the displacement of the heart in the presence of a very moderate degree of effusion. An important corollary to the same proposition is, that cardiac displacement is not to be held to indicate a very large amount of effusion. On the contrary, it is one of the earliest symptoms, and observable while the effusion is yet quite small.

Dr. Garland, in his most ingenious monograph on Pneumono-dynamics,[1] quotes Skoda as expressing the same opinion on the cause of cardiac displacement. Nevertheless, it is unquestionable that the majority of writers continue to speak of the displacement of the heart by pressure of the effusion.

It is easy to verify by experiment Dr. Powell's statement—that cardiac displacement occurs with very small effusions, and soon after they are poured out. Indeed, in the experiment, where the effusion is necessarily sudden, the displacement is equally sudden. Thus, in an etherized dog, having ascertained that the cardiac apex was in its normal position, I injected—through a glass canula, fitting air-tight—seventy-five cubic centimetres of warm water into the left pleural cavity at the anterior axillary line, and in the seventh intercostal space. Three minutes later the heart was found to be visibly and forcibly pulsating at the right of the sternum. A respiratory tracing taken immediately, with a tambour placed over the right side of the chest, shows a great amplification of the respiratory excursion, both in inspiration and expiration.

Tracing No. 1 contains (*A*) a normal tracing taken before any operation, and (*B*) a tracing taken immediately after plunging one arm of a fine glass T-tube into the left pleural cavity.



In this experiment the tissues were incised down to the internal intercostal muscles and the glass tube plunged into the pleura. The facility with which this can be done shows the rapidity with which the lung retracts with its visceral pleura, so that the virtual cavity is instantaneously converted into an actual one. Were not this the case, it would be almost impossible to open the pleura without wounding the lung. The following tracing shows

the effect on respiration of opening the pleura in the way described—the inspiration on the uninjured side becomes more ample, as is seen in tracing No. 3.

[1] Pneumono-dynamics: Boston, 1878.

The fourth tracing, taken after injection of seventy-five centimetres of warm water, shows that this amplitude is still further increased.

As Dr. Douglas Powell remarks, the heart is so movable that its displacements may serve as a most delicate and accurate measure of any perturbation in the normal intra-thoracic equilibrium of forces—that is, of balancing tractions. It is interesting to notice that while a diminution in the elastic traction of the lung, which coincides with a pleural effusion, allows the heart to be displaced—*i. e.*, drawn over to the opposite side—diminution of elasticity due to solidification and diminution of size, as when lung tissue collapses over an empty cavern, is followed by displacement of the heart toward the affected side, so that marked lateral and upward displacement of the heart is an important sign of contraction of pulmonary caverns, and, to a considerable extent, measures their rate of progress to healing. But in this case the heart follows the negative pressure determined by the potential vacuum which exists, when the lung tissue tends to retract from the thoracic wall. When there is a pleural effusion there is no potential vacuum, for the fluid completely fills all the space left by the retracting lung, and the amount of fluid and amount of pulmonary retraction are necessarily exactly proportioned to each other. It is only in this sense that the fluid can be said to favor directly the cardiac displacement. Its principal effect is indirect, and exerted through the lung, which, in presence of the fluid, loses a portion of its power of elastic traction.

This last remark brings me to another very interesting and much debated problem of pleural effusions, namely, the precise effect exercised on the lung by the fluid in the pleura.

The same line of thought which leads to the view that the heart is displaced by pressure, sustains the current theory that the lung is "compressed" by the effused fluid. Indeed this theory is habitually taken as a matter of course, and as not needing discussion. Nevertheless, as soon as we begin to reflect on the nature of the lungs, and of the forces which maintain them expanded in the thoracic cavity, it seems to me remarkable that the true view of the case should have remained so long undiscovered The first demonstration of this view that I have read, was given by Dr. Garland, of Boston, in 1878, and is admiringly adopted by Dr. Douglas Powell. This view reposes upon obvious theoretical considerations; upon the results of experiments with inflated balloons in glass vessels, where the physical conditions of pleural effusions are imitated with surprising accuracy; finally, upon

the results of injections into the pleural cavity of dogs made with fluids capable of solidification, and which form permanent moulds *in situ*, and thus indicate the course taken by the injection in the fluid state.

The theoretical consideration is that the lungs are highly elastic bodies, normally maintained in a state of extreme tension by the pressure of the air contained in them, and which, while the pleural surfaces remain in contact, is counteracted by nothing. The atmospheric pressure hence acts with full force, and keeps the lungs exactly applied to the walls of their containing cavity, except in the complemental space at the base, reserved for forced inspiration. But if either air or liquid be admitted into the pleura, the internal atmospheric pressure within the pulmonary cavities, the bronchi, and air-cells, is counteracted to an exactly proportionate extent. To the same extent to which the pressure of the air is diminished, is the elastic tissue of the lung able to return from the over-stretched conditions into which it had been put by the unopposed pressure of the air. Like any other elastic body, the lung tends to return to its original size as soon as the distending force is withdrawn. In the case in question, the distending force is not withdrawn, but it is partially neutralized. To the same extent does the elasticity or retractility of the lung come into play: it retracts upon its contained air.

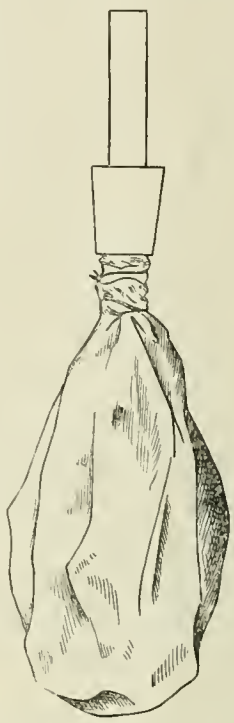
As in every interplay of physical forces, the effective condition of this phenomenon, the retraction of the lung, cannot be considered its efficient cause. The effusion does not precede in time the retraction; but the two phenomena march *pari passu* together. The efficient cause of the retraction of the lung is the elasticity of its tissue, which comes into play as soon as the obstacles to its manifestation are removed. The effusion removes the obstacle by neutralizing to a greater or less extent the pressure of the air. It is, therefore, the condition upon which the manifestation of the retractile power of the lung depends; but by no means the efficient cause of the retraction or of the diminution of size.

An elastic body cannot be compressed until its elasticity is exhausted.

So long as any elasticity remains, the body exercising pressure can only neutralize atmospheric pressure, and allow the over-stretched elastic body to return upon itself. The pressure allows this; it does not compel the reduction of the body to a small size, as is done when inelastic bodies are compressed, by forcible approximation of their molecules.

This theoretical exposition is well illustrated by Garland, by means of such a little apparatus as is here shown. It consists of a pear-shaped flask, surmounted by an opening closed with a rubber cork, and terminating below in a long tube, through which passes a stop-cock. Within the flask is suspended a thin rubber balloon, attached to a glass tube, which passes air-tight through the rubber cork. The stop-cock and tube at the lower

Fig. 1.



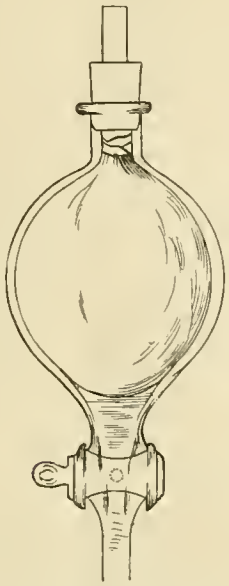
Balloon around glass rod, before insertion into flask.

part of the flask are filled with water, by immersing the tube in water to above the level of the stop-cock, while the cork is out of the flask. The tube is then plunged under water, the stop-cock opened, the cork inserted tightly, and the balloon inflated through the glass tube until it fills the flask. If the size of the balloon and the flask corresponded accurately, the balloon would adapt itself accurately to the walls of the flask. As it is, the adaptation is exact enough to fulfil the conditions of the experiment. See Fig. 2.

The stop-cock may then be closed and the apparatus be lifted out of the water without causing any change. The balloon remains inflated, for, though its cavity communicates freely with the open air, the column of water remains in the lower tube. If now, while this lower tube is plunged to a greater or less extent under water, the stop-cock be opened, the column of water in the tube will be subjected to the pressure of the water in the vessel—pressure which increases with the depth of immersion. At a certain depth there will be no change, for the column of water below the balloon will be equal to the pressure of the atmospheric air within. If the tube

be plunged lower, the pressure of the column of water will become equivalent to a part of the pressure of the air, and will neutralize it. To exactly

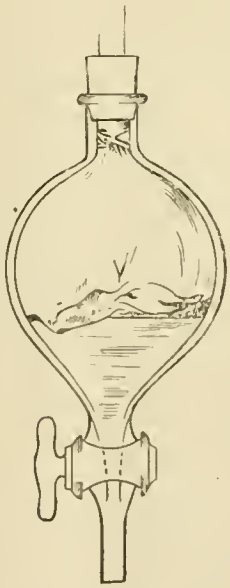
Fig. 2.



Flask with balloon expanded and filling flask. Tube filled with water, and then closed.

the same extent will the balloon be relieved of a certain degree of tension, and return upon itself

Fig. 3.



Flask after some water has been admitted by turning the stopcock while nozzle under water. Balloon retreated and partly collapsed.

proportionately. Thus, as Garland expresses it, the "balloon flees before the advancing column of water," and must continue to do so until its retractility is exhausted, and the flask is exactly filled by water plus the collapsed balloon. In this condition it would be impossible to aspire water into the flask, as had previously been done while the balloon was retracting and exerting a negative pressure upon the column of water. But if more water were injected forcibly into the full flask—as it could make no room for itself against the rigid walls—it would, with a *point d'appui* taken upon them, press upon the balloon until the compressibility as well as the elasticity of the latter was exhausted. The same thing may happen with pleural effusions, but only under one of two circumstances. The effusion may be exceptionally abundant, or the lung may have been already consolidated by disease, and thus, at the outset, deprived of its elasticity, and, therefore, exposed to compression much earlier in the course of an effusion.

Observation of this simple but instructive apparatus illustrates some other circumstances. As the balloon retracts, returning upon itself from the condition of over-distention, it becomes flaccid. It is to an analogous flaccidity of the lung that Weil has attributed the phenomenon of tympanitic percussion resonance often heard over the lung above the level of a pleural effusion.

The stomach, whose walls are flaccid, gives a tympanitic resonance which, as every one knows, contrasts markedly with the much lower percussion note of the normally distended lung. It is easy to demonstrate experimentally, as I have myself done before a class, by inflating the excised lung of a calf or sheep, that, when inflation was complete, percussion yielded the normal tone; but if air was allowed to escape from the lung, percussion gave a tympanitic sound. According to Weil, in the distended lung the walls of the air-cells do not vibrate with the vibrations of their contained air; but in the relaxed lung, as in the stomach and intestine, the walls of cavities containing air are thrown into vibrations whenever the air vibrates; and the coincident vibrations of heterogeneous bodies result in the tympanitic sound.

Another point deserving notice in the apparatus is the reëxpansion of the balloon if water be allowed to run out through the inferior opening. The balloon reëxpands as rapidly as it had retracted. It is drawn by the negative pressure of the water potentially; the efficient cause of the reëxpansion being the pressure of the internal air, when a tendency exists to form a vacuum, as the water falls away from the balloon. This phenomenon is of great importance in understanding the reëxpansion of the lung after operations for the removal of a pleural effusion. I will return to it again. In describing the condition of the child previous to operation, I have said that the region

of absolute dulness reached the second rib in front and the spine of the scapula behind, and was bounded superiorly by a horizontal line. There did not exist the curved, or letter S line, discovered and described by Dr. Ellis, of Boston. According to this line, the region of absolute dulness is highest in the axillary line, and thence descends toward the median line, to the sternum in front, to the vertebral column behind. Dr. Peter, of Paris, interpreted this line as an indication of a purulent effusion, which, being more viscid than a serous fluid, would adhere in places to the thoracic walls, while the serous fluid would assume the hydrostatic level. It is unnecessary to discuss this theory, for it has been abundantly proved that the curved line can be distinguished by careful percussion when the effusion is serous as well as when it is purulent. But Garland, in seeking to explain the *rationale* of this elevation of the fluid in the axillary line, has ingeniously demonstrated the value of the curved line as a measure of the remaining retractility of the lung—as a measure consequently of the amount of effusion.

Since the elevation of one part of the upper surface of a mass of liquid is contrary to hydrostatic laws, it is clear that these must have been thwarted by some special force acting in opposition to them. Fluid cannot rise above its own level, and if it is found above it, it must have been driven or pushed up. Now it has already been shown, and elegantly illustrated by the balloon and flask apparatus, that during the early stages of a pleural effusion, while the lung is retracting, it necessarily aspires the fluid in contact with it, by virtue of negative pressure. The force of retraction is greatest where the extension has been greatest, hence first and most powerfully exercised from below upward. Subsequently, the lung also begins to retract in its transverse diameter, or from the external thoracic wall toward the lung root. In so retracting, a virtual vacuum is created between the lung and the chest wall, and into this the fluid rises. It rises first and higher in the axillary line, because the force of retraction is greater in the transverse diameter of the lung than antero-posteriorly. Correlatively, as long as the region of absolute dulness is confined to the inferior and axillary portions of the chest, and the diaphragm is not depressed, we may infer that the effusion is moderate, and that the lung retains much retractile, hence much expansile, power. Even when absolute dulness has spread over the anterior and posterior regions of the chest, the fluid may be known to have followed the lung, so long as its upper border presents a curved line. But if the lung reaches its furthest limit of retraction, it ceases to aspire the fluid, or to hold this above its normal level, which is a horizontal line.

Contrary, therefore, to the theory of Peter, the maintenance of the curved line, incapable of distinguishing the nature of the fluid, does indicate moderation in its amount, and preservation of good retractile power in the lung; while the substitution of a straight line, indicating the natural level of the fluid, shows that the effusion is extensive, and the lung on the point of being compressed.

Garland tested the respiratory force of the lung by means of injections, into a dog's pleura, of cocoa butter, which was allowed to remain there until complete solidification. Examination of the moulds thus formed showed that, whether the injection had been made with the dog in a horizontal position or suspended vertically, the fluid had risen above its hydrostatic level, and formed a curved line projecting toward the axilla. I have imitated this experiment and obtained similar, though less striking, results, as the amonnt of cocoa butter injected was smaller.

(*To be continued.*)

PROPOSED LEGISLATION RELATING TO THE MEDICAL PORTION OF THE PENSION BUREAU.

BY HENRY BIXBY HEMENWAY, M.D.,
OF KALAMAZOO, MICH.

IT is not a matter of indifference to the general profession how any portion thereof is regarded and treated. The disgrace of a single man is a disgrace upon the fraternity. A physician doing public service is almost without exception illy paid. How many health officers receive compensation proportionate to the work done? No one would think of letting the position of city or county attorney to the lowest bidder, and yet in a wealthy and intelligent community, at no distant period in the past, the position of county physician was given to the lowest bidder, after advertising for proposals. While attorneys may regulate admission to the bar, a like privilege is not granted to physicians. Because many knaves with little education secure large patronage, the people depreciate the medical service. Two boys set out, the one to study medicine and the other law. The lawyer is admitted to the bar at the end of two years, after having been able to pay his expenses by legal writing while studying. The doctor must be at constant expense for three full years before he is entitled to earn anything by his profession. Each is then called upon for a like amount of public service. The lawyer's bill is promptly audited, while the authorities hesitate to allow one-fourth as much to the doctor. Such conduct toward our profession is belittling and degrading. It is therefore time that the whole profession should be aroused to act in harmony.

The attention of the profession at large has occasionally been directed to pension lesislation. Dr.

P. S. Connor, of Cincinnati, read a paper before the American Academy of Medicine, at Pittsburg, 1886, in which he urged the appointment of forty boards of examining surgeons, each consisting of two members, who should devote their entire time to that service. His paper was published in the *Journal of the American Medical Association* (vol. vii. p. 570). Dr. L. Brown, of Pottsville, Iowa, in the same journal for January 1, 1887, criticised this paper at length, but he omitted to say that such a special service would not attract men of large experience, and lacking that, the examiners would be dogmatic and theoretical rather than practical. I might give illustrations of this, drawn from the work done in the Washington office, had I the space.

On the other hand, it is not desirable that boards be too greatly multiplied; first, because from lack of available material from which to construct boards, the quality of the work done must deteriorate; and, secondly, if the work is so decreased as to diminish materially the pay of members, the position cannot command the best talent.

In this same journal for Oct. 27, 1888, is an article by Dr. John W. Wright, of Columbus, read before the Section on Ophthalmology at the meeting of the Association in 1888, on "A Plea for the Better Recognition of the Oculist in the Service of the U. S. Pension Department." A like plea might be made for all specialists treating diseases of men. It simply shows hows how preposterous it is to attempt to establish a board at every country cross-roads.

Pension applicants are examined only when ordered by the bureau, or by a "special examiner." (The "special examiner's" work is purely legal, and cases are put into his hands in which the evidence is conflicting or doubtful.) Examination orders are issued in duplicate, one going to the applicant and the other to the particular board or single surgeon before whom the case is ordered. An order is to be obeyed by the applicant and honored by the surgeon within three months from date of issue. At the end of that time, orders remaining in the hands of the surgeon are returned with the endorsement, "failed to appear." The order to the surgeon gives the statement of claims. When it is impossible for the examination to be made by a "board," the Commissioner orders a single surgeon to visit the applicant and make the examination.

The boards, or single surgeons, do not grant the pension, or pass upon the legality of the claim. Evidence as to the degree of disability, or to the cause thereof, have no value for the board. That should be sent to the bureau. The work of the examing board consists of making a record of the present physical condition of the applicant, with an estimate of the degree of disability from each cause, including senility. Formerly the examination was only with reference to the special claims. Under the late medical referee, as well as the present, all disabilities have been examined, whether originating in the service or not. The record made is called the "certificate of examination."

In the Washington office the force consists of one medical referee, one assistant, two surgeons, and eighteen medical examiners. These men receive each per annum, respectively, $3000, $2500, $2000, and $1800. The completed certificate is first examined by one of the eighteen medical examiners, later by a surgeon and the medical referee or his assistant. In passing upon the case, the examiners have before them all the papers in the case, often including several certificates of examination. Can it be expected that a dozen and a half medical examiners should carefully judge all the certificates for the country? Is it strange that when the magnificent salary of $1800 is paid each examiner, incompetent assistance should be secured. Dr. Wright's remark really applies more forcibly to the Washington office than elsewhere.

A certificate of examination must be in the handwriting of a member of the board. It gives the name, rank, service, and post-office of applicant, number of his claim, date of examination, and post-office of board, disabilities for which pension is claimed, pulse rate, respiration, temperature, height, weight and age of applicant, and applicant's statement. These are followed by results of examination, and ratings of each disability. If the claim is on diarrhœa, for example, the certificate must show the condition of tongue, teeth, gums, skin, liver, spleen, stomach and intestines, and heart. "The rectum must be explored digitally or with speculum," and any fissure, fistula, hæmorrhoid, or prolapse must be carefully described. As to heart, it is required to give location of apex beat, area of dulness and position, character of impulse, character of sounds, exact location of bruit as to time and valve, dilatation or hypertrophy, dyspnœa, œdema, or cyanosis. If disease of kidneys is affirmed (which generally means simply lumbago), the condition of all vital organs must be stated, with chemical and microscopical examination of urine and opthalmoscopic examination of the eye. Gunshot and other injuries, neuralgic tracts, etc., must be shown by a diagram. Every certificate must be signed by each member upon its face and back, and it must be copied verbatim into the record book, and the copy also signed by each member.

It will therefore be seen that the work is not small—is, in fact, many times greater than that required by any life insurance company. It is not allowable for one member of a board to make the examination. All must participate. Boards vary

greatly as to capacity for work. One may examine thoroughly twenty men, while another is going through five cases. This capacity for work depends upon system and concentration. Since it takes more time to write the certificate than to make the examination, much depends upon the speed of the writer. It is not allowable to have a clerk. Twenty examinations is a legal day's work, and as a rule it is a full day's work. A good certificate must be short, concise, clear, and complete.

Aside from any writing that may be done at the meeting of the board, it is expected that the secretary shall transcribe the certificate into the record book, back the certificates (for filing), make out the daily and quarterly reports, and attend to the correspondence of the board. For each day's work there must be made out one daily, and two quarterly reports. These reports give, for each applicant, date of examination, name of applicant, character of claim, number, and services, and the fee of each examiner. The names must be arranged in two alphabetical series. For a day's work of twenty examinations made by the Kalamazoo board, the word "Kalamazoo" must be written sixty times on the certificates and fifteen times on reports; total, seventy-five times. It may occur more times. The date must be written 102 times for the same work, and each member must sign his name forty-three times. No stamping is allowed.

Surgeons are supplied with the blank forms of the office, and envelopes addressed to the Commissioner. They must supply other stationery, pay postage on all correspondence, except with the Commissioner, and furnish an office with the necessary instruments for making the examinations in accordance with modern science.

Prior to the act of March 3, 1885, surgeons received two dollars for each examination. That act reduced the compensation so that now surgeons receive two dollars each for each examination up to five, and one dollar each on further examinations up to twenty, examined on the same day. There is no legal compensation for the extra labor devolving upon the secretary of the board. Many boards, however, agree upon certain concessions. Some pay the secretary five or ten dollars per quarter; others ten per cent. of the receipts of the board; others still, ten to twenty-five cents per examination.

The present small compensation is made still smaller by delay in auditing and paying accounts. On October 23, 1889, the accounts for the board of which the writer is a member had not been audited for the quarter ending June 30th.

A meeting of examining surgeons was held in the Pension Building during the International Medical Congress, September, 1887. After a general discussion, it was resolved unanimously that the present compensation is far too small, and Congress was asked to restore the former fee. At the request of Dr. Campbell, medical referee, I drafted two bills, which were introduced before the lower House by the Hon J. C. Burrows. The first of these relates to the medical staff in the Washington office, and reads as follows:

A BILL

To increase the efficiency of the Medical Division of the Pension Bureau.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That the medical staff of the Pension Office shall consist of one medical referee, one assistant medical referee, three surgeons, and twenty-four medical examiners.

SEC. 2. That the medical referee shall be a man of preëminent professional ability, and shall receive the sum of four thousand dollars annually. He shall be the chief of the Medical Division, and as such shall oversee and arrange the work of said division.

SEC. 3. That the assistant medical referee shall also be of preëminent professional ability, and shall receive an annual salary of three thousand and six hundred dollars,

SEC. 4. That the three surgeons shall be experts in their profession, and shall each receive an annual salary of three thousand dollars.

SEC. 5. That the medical examiners shall be surgeons of education, skill and experience, and shall receive each an annual salary of two thousand and five hundred dollars.

SEC. 6. That all former acts or portions of acts conflicting with the provisions of this act are hereby repealed.

SEC. 7. This act shall take immediate effect.

It adds one surgeon and six examiners to the present force, and increases their salaries as follows:

Medical Referee, from $3000 to $4000. Assistant Referee, from $2500 to $3600. Surgeons, from $2000 to $3000. Medical Examiners, from $1800 to $2500.

As originally drafted, at Mr. Burrows' suggestion the salary of medical referee was $5000 and his assistant $4000, but Dr. Cambell asked that they be cut down as above to assist in the passage of the bill.

The second bill relates to boards of examining surgeons, and reads:

A BILL

To increase the efficiency of Boards of Surgeons for the examination of pension applicants.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That each member of each board of surgeons for the examining of applicants for pensions, shall, as now authorized by law, receive the sum of two dollars for the examination of each applicant.

SEC. 2. That the secretary of each board of surgeons

shall receive a further compensation of fifteen cents for each examination.

SEC. 3. That the secretary of each board of surgeons shall be, and hereby is, empowered to employ a clerk, and for the official conduct and pay of such clerk the said secretary shall be responsible.

SEC. 4. That all former acts, or portions of acts, in conflict with the provisions of this act, are hereby repealed.

SEC. 5. This act shall take immediate effect.

Dr. Campbell thought that section 2 ought to say twenty, in the place of fifteen cents. So far as examining boards have been heard from, all agree that it should say twenty-five cents, and when the bill is again introduced, this change will be made. It must be noticed that section 3 does not add any expense, but makes legal the employment of a clerk by the secretary.

Mr. Burrows has introduced these bills before the present session of Congress, and Mr. Stockbridge will present them in the Senate. It is therefore hoped that *every* physician, whether in the government service or not, will, *without delay*, write to his Representative and Senator in support of these bills. It is not claimed that the pay here proposed is such as it should be, but it is better than at present. If all will give their aid, the changes may be accomplished. If the present low rate of compensation is continued, the service must deteriorate. Imperfect work necessitates more frequent re-examinations, and justice to the pensioner is impossible.

HOSPITAL NOTES.

ANTISEPTIC IRRIGATION FOR SYNOVITIS OF THE KNEE. IMPLANTATION OF MUCOUS MEMBRANE IN TRAUMATIC STRICTURE OF THE URETHRA. IMPLANTATION OF BONE.

Abstract of a Clinical Lecture Delivered at the New York Hospital.

BY ROBERT F. WEIR, M.D.,
ATTENDING SURGEON.

DR. WEIR alluded to a case of chronic serous synovitis of the knee on which he had operated at the previous clinic. The fluid in the joint had been evacuated, and the joint repeatedly washed out with a 1 : 20 solution of carbolic acid under strict antiseptic precautions. After applying the usual dressing the limb was placed in an immovable apparatus. He called attention to the thickening that occurs around the joint after this procedure, and which is sometimes accompanied by some accumulation of fluid. So long as there is fluid the patient should not be allowed to go about; but when the thickening alone exists it may be disregarded, for it will slowly disappear while the patient is moving around.

He then presented a case of traumatic stricture of the urethra which had not yielded to the usual methods of treatment. The patient, a boy, thirteen years of age, sustained an injury to the perineum a little over a year ago; and following this, there was sloughing of the perineum and extravasation of urine, resulting in stricture and difficult micturition with a perineal fistula necessitating the operation of external perineal urethrotomy, which was performed on the patient in the winter of 1889–1890 by Dr. W. T. Bull. There was always great difficulty in passing an instrument, and the contraction recurred to such an extent as to demand a second operation, which was performed by Dr. L. A. Stimson in August. At the time of leaving the hospital, and for about two months afterward, the boy urinated through the natural channel, but no instrument could be passed into the bladder. Then the old perineal fistula broke open, and from that time on the urine was voided through this opening. Ordinarily, Dr. Weir remarked, traumatic stricture occurs anteriorly to the triangular ligament; but occasionally, chiefly as a consequence of blows or kicks received from behind, the injury is in the membranous portion, and very rarely in the prostatic portion, one instance of which was briefly alluded to. From a rectal examination of this case, there was little doubt from the thickening of the tissues found that the injury extended behind the triangular ligament. It was found on passing an instrument through the meatus to the middle of the perineum, and cutting down upon it, that a probe from that point passed only a very short distance without complete obstruction; an instrument was finally passed from the perineum upward into the bladder, and the urethra near the prostate was gradually enlarged from the size of a No. 10 French bougie until sufficient room was gained to admit a No. 30 sound. While doing this much cicatricial tissue was encountered both anteriorly and posteriorly to the urethra. The space between the anterior urethra and the posterior portion was then cut through the median line, and by division of the meatus, a No. 26 sound was passed in from that direction to the bladder. As the stricture had proved so obstinate under treatment, and showed such a strong tendency to recur, it was thought that benefit might accrue from replacing the mucous membrane which had been destroyed for about half an inch or more on its upper surface, and to an extent of nearly an inch on its lower aspect, by one of the grafting processes.

Wölfler, a former pupil of Billroth, stated before the Society of German Surgeons, in 1888, that he had been able to transplant mucous membrane with as much ease and success as was commonly met with in skin-grafting. It was only necessary that some means should be found which would secure adhesion of the pieces of mucous membrane for a short time in order to obtain the desired result. He had three times resorted to this method for impermeable stricture of the urethra, and in these cases had made use of pieces of mucous membrane from a prolapse of the rectum or of the uterus; but he had found that mucous membrane from some of the lower animals would answer the same purpose. He had employed the mucous membrane from the œsophagus of a pigeon, or from the œsophagus or bladder of a guinea-pig, because in these animals the mucous membrane is readily removed from the submucous tissue. It could certainly do no harm to resort to this method in the present instance, and it might be productive of much good.

The operation had been performed four days previously, as it was considered that the grafts would be better applied after granulation had become established than on a bleeding surface.

Pieces of mucous membrane just removed from the œsophagus and bladder of a guinea-pig were then inserted in the perineal wound and retained in place by several fine sutures. A soft catheter was then introduced into the bladder, which smoothed out the wrinkled mucous membrane, and in addition held it *in situ*. This was fastened in position, and the wound lightly packed with iodoform gauze.

It is extremely difficult to say what will be the success of this procedure; but it must be remembered that the certainty of relief can only be definitely determined after the lapse of a number of months.

Dr. Weir then directed the attention of the class to the method of filling up large bone cavities by the implantation of small pieces of bone; and presented a patient, who two weeks before had been subjected to an operation for necrosis of the lower end of the tibia. The cavity left after the removal of the large sequestrum had been filled with pieces of decalcified bone, according to the method advocated by Senn, of Milwaukee. The operator had doubted the success of the operation both on account of the difficulty of securing a thoroughly aseptic cavity in this particular instance, and because he had not yet been able to understand how, under such circumstances, decalcified bone, catgut, or any similar material could be converted into new bone. He could readily believe that the material when introduced might act as a skeleton or framework for the new vessels, until these delicate structures were strong enough to live without such support. The dressing had not been disturbed for two weeks, and everything had apparently done well; but on removing the dressing, it was found that every one of the pieces of decalcified bone had dissolved and come away in the discharge from the wound. Notwithstanding this failure in grafting, there had been some organization of the blood-clot, and the cavity was considerably smaller than is usually found after the lapse of two weeks.

He proposed, in a similar case, which he was now about to bring before the class, to adopt another method of implantation of bone, and in doing this, he would be guided by the experience of Macewen, who was one of the pioneers in this department. The process consists in filling the bone cavity with very small pieces of bone which have been removed from a recently killed dog, selecting grafts, according to the suggestions of Poncet, from the neighborhood of the epiphyseal line, because of the greater nutritive activity there.

The patient was a tailor, thirty-seven years of age, who for twenty-four years had been troubled by disease of the left tibia, with occasional abscesses of this part. He was rather poorly nourished, and there was an opening on the outside of the left tibia just above the middle, which connected with the interior of the bone. It was probably a case of chronic bone abscess.

On chiselling away a little of the diseased bone, an abscess deep down in the bone was exposed. After removing the diseased tissue, and thoroughly scraping and cleansing the resulting cavity, some three inches long, one and a half inches wide, and the same in depth, small pieces of bone were introduced according to the method already described. The fragments were freely dusted with iodoform, the skin brought together with interrupted sutures, and the usual antiseptic dressing applied.

MEDICAL PROGRESS.

Treatment of Tubercular Arthritis with Injections of Iodoform.—DR. FEDOR KRAUSE has recently treated several cases of tubercular disease of the joints with injections of the following emulsion:

R.—Iodoform	5	parts.
Mucilage of acacia	2.3	"
Glycerin	8.3	"
Distilled water	50	"

The injections were practised only on cases of severe tubercular arthritis in whom cure without operation seemed impossible. If an abscess of the joint existed the pus was withdrawn by means of a trocar, the cavity being thoroughly washed out with a 3 per cent boric acid solution. Through the trocar opening the iodoform mixture was injected, after which passive motion was used in order that the iodoform should be brought in contact with all parts of the articular surfaces. The injections are only slightly painful, but a rise in temperature for one or two days occasionally follows. The results, Krause claims, are good, and the method is worthy of a more extended trial.—*Centralblatt f. Therapie*, January, 1890.

Suturing an Intra-capsular Fracture of the Femur.—Another case is reported from Italy in which PROFESSOR LORETA has sutured an ununited fracture of the neck of the femur. The patient, who was about forty years of age, had suffered considerable pain in the joint, the fracture having occurred more than a year previously. A long incision was made behind the great trochanter, and the capsule of the joint exposed as though an excision was to be performed. The capsule was incised and the ends of the bone scraped to promote union. The fragments were then brought in close apposition with twelve metallic sutures, the ends of which were brought out of the wound, so that they might be removed later. The wound was thoroughly irrigated, after which a drain and the usual sublimate dressing were employed. The limb was kept at rest by means of an external splint, and a few days after the operation the wires were withdrawn. A good recovery with a useful limb resulted.—*Illustrated Medical News*, December 14, 1889.

Further Observations on the Use of Antipyrin in Whooping-cough.—In connection with the diverse opinions upon the value of antipyrin in whooping-cough the observations of WINDELSCHMIDT, of Cologne, are interesting. This author has treated a series of 350 cases with antipyrin. The results in one-half of the cases were good, the duration of the disease being reduced to two or three weeks. In 30 per cent. of the cases either no results followed the administration of the drug, or the patients withdrew from treatment. In the remainder the antipyrin had a well-marked sedative effect. Windelschmidt considers that for this method of treatment to be effective it should be

begun early in the case. The dose employed was one and a half grains for each year of the patient's age three or four times daily.—*Centralblatt f. Therapie*, January, 1890.

The Significance of Urobilinuria.—M. Hayem considers that urobilinuria, when habitual, persistent, and varying in degree, has a clear pathological significance, and is a valuable indication in forming an early diagnosis in diseases of the liver. He regards urobilin as the characteristic coloring matter of hepatic incompetency. He has observed urobilinuria in the following diseases: 1. At the beginning of alcoholic cirrhosis. 2. In patients with cardiac disease in whom the liver is not enlarged it may be an indication of incipient hepatic lesions. 3. In numerous acute affections, when observed in alcoholic patients, such as typhoid fever. When a large proportion of urobilin is detected in this affection, reserve should be made with regard to the prognosis. 4. In newly delivered and nursing women. 5. In most forms of cachexia. Urobilin has a feeble coloring power, and is found in pale urine. The deep coloring of urine observed in certain affections (fever with perspiration, lassitude, overfatigue) is usually due to urochrome.—*British Medical Journal*, January 4, 1890.

[The following are Professor Tyson's directions for testing for urobilin: Add ammonia to the urine until distinctly alkaline, filter, and to the filtrate add a little chloride of zinc solution. The appearance of a green fluorescence indicates the presence of a considerable amount of urobilin.—Ed.]

Acute Pancreatitis.—Langerhaus recently reported a case of acute pancreatitis before the Medical Society of Berlin. The patient, aged fifty years, became suddenly ill with vomiting, headache, giddiness, and weakness. During the following night the abdomen became markedly tympanitic and he suffered somewhat from dyspnœa. Cold applications temporarily reduced the tympany, which, however, soon returned accompanied with severe pain in the left hypochondriac region. When admitted to hospital an indurated swelling was observed above the umbilicus extending obliquely across the abdomen. The patient's temperature was slightly elevated; the pulse was weak and a few "rose" spots were discovered. The case was diagnosed typhoid fever. For some time the condition of the patient was but little changed. There was occasional but not violent vomiting for several weeks, when it became more frequent, the ejecta having an offensive odor. Finally, unconsciousness and death supervened. At the autopsy the pancreas was found completely necrosed and lying in a cavity formed by the distorted and adherent abdominal organs. It is to be noted that the duration of this case was more than eight weeks, most cases of acute pancreatitis terminating much earlier.—*Deutsche medicinische Wochenschrift*, December 12, 1889.

Unna's Treatment of Tinea Tonsurans.—Unna believes chrysarobin to be the most useful remedy in all parasitic diseases of the skin. In tinea tonsurans the drug is not much used by most dermatologists from the fear that the drug may reach the eyes, where it causes severe inflammation. Unna has devised the following method of applying it which eliminates this danger: First, the hair around the affected areas is cut off, not shaved. Then a band of zinc oxide and glue is painted across the forehead, above the ears, and around to the back of the neck. Following this a chrysarobin ointment is carefully spread upon the diseased scalp, the ointment which he uses being composed of:

Chrysarobin	5 parts.
Salicylic acid	2 "
Ichthyol	5 "
Simple cerate	100 "

Or a simple 5 to 10 per cent. chrysarobin ointment may be used. A broad strip of gutta-percha paper is passed around the head in such a manner that the lower edge adheres to the oxide of zinc glue. This impermeable paper is then painted with glue and covered with a mull bandage, and over the whole a flannel cap is placed. The latter may be sewed to the mull bandage. Every twenty-four hours the cap and bandage are removed, and the gutta-percha paper cut to obtain access to the scalp, which is then cleaned, smeared with fresh ointment, and covered again with a new mull bandage and flannel cap. If the ointment finds its way through the dressings it must be carefully wiped off and the soiled portions thoroughly painted with oxide of zinc glue. Thus carefully protected, the child may be allowed to mingle with healthy children without danger of infecting them.

In four days the outer dressings are removed and the chrysarobin ointment replaced by a five per cent. ichthyol salve, which will dissipate the superficial irritation caused by the chrysarobin. At the end of the first week all the dressings may be removed and the scalp washed with oil and soap. The diseased parts are then seen to be of a lighter color than the surrounding skin.

The entire treatment is to be repeated three or four times, but Unna has never found that a fifth cycle of treatment was necessary to effect a complete cure.—*Monatshefte für Praktische Dermatologie*, Dec. 1889.

The Use of Papain in Suppurative Otitis.—Dr. McKinzie Johnston, of Edinburgh, writes that in chronic suppuration of the middle ear pain is an almost certain indication that the secretion has not free exit, which may be due to the smallness of the perforation, the viscidity of the pus, or to obstruction by growths or by hardened masses of dry pus, débris, or cholesterin. It is well known that if these conditions are neglected there is grave danger that the retained septic pus may lead to an extension of disease, possibly necessitating an operation for mastoid abscess, or even for cerebral abscess. It seems, therefore, evident that anything which will facilitate the cleansing of the middle ear, and readily dissolve hard masses of débris, etc., must of necessity decrease the risk of these serious consequences. In papain we have a drug capable, by its digestive action, of thoroughly cleansing the ear in those cases in which simple syringing is insufficient. Dr. Johnston has tried it now in a number of cases, and apparently with most satisfactory results. Of course, it is impossible to say that any one of these cases would have gone on to mastoid disease had they not been so treated, but cleansing of the ear was rapidly effected, and in one or two cases the relief of the pain was most marked.

The following is the way he employs the drug: 15 minims of a 5 per cent. solution of papain are dropped

into the ear, care being taken that it reaches the bottom of the meatus. If necessary, the patient may be made to swallow while holding the nose, so as to draw the fluid in the middle ear. Mindful that bacteria develop largely in fluids acted on by this drug, it should be allowed to remain for one hour only, after which the ear is syringed out with boric lotion and carefully dried. This may be repeated as often as necessary.

This plan of treatment seems especially suitable to long-standing cases where there is only a little thin and very foul-smelling discharge, probably associated with diseased bone.—*Edinburgh Medical Journal*, January, 1890.

Ehrlich's Reaction.—DR. BACNACCI, assistant in Bufalini's clinic, has recently made a number of careful observations on Ehrlich's diacetone reaction. His studies included the urine of patients suffering from several different diseases. In cases of advanced phthisis the reaction was occasionally present, but not constantly. In the urine of patients suffering from pneumonia, variola, acute enteritis, and typhus fever, the test was usually negative. In diabetic urine the reaction could almost invariably be demonstrated. The reaction was also present in the urine of patients who were taking either iodol, sozoiodol, thymol, or strychnine. In diabetic urine which had been subjected to prolonged boiling the reaction could no longer be detected.

The author considers it probable that the reaction bears some relation to the sugar and acetone present in diabetic urine.—*International klinische Rundschau*, December 8, 1889.

[Ehrlich's or the diazo-reaction was first announced as a diagnostic sign of typhoid fever, and consists in adding to the suspected urine a solution of sulfo-diazo-benzol, then a solution of ammonia. If the reaction occurs, the mixture becomes at first deep red, which is followed by the precipitation of a dull green sediment.—ED.]

The Staining of Amyloid Tissues.—BUCHARDT describes the following new method of staining amyloid tissues in Virchow's *Archiv*:

Stain the sections in a moderately strong solution of gentian-violet in aniline water. Decolorize in a solution of hydrochloric acid (1 : 10) for ten minutes. The amyloid portions of the tissue are then a dark purple, the other portions colorless. Then wash in water and clear up in a solution of potassium acetate.—*Centralblatt f. medicinische Wissenschaften*, December 14, 1889.

Creolin Pills.—According to *L'Union Médicale*, the following is a convenient formula for the internal administration of creolin:

℞.—Creolin . . . . . 1½ drachms.
Dilute alcohol . . . . 15 minims.
Extract of liquorice, Pulverized liquorice, of each, 1½ drachms.
Tragacanth . . . . . 15 grains.—M.
Make in one hundred pills.

Pharyngitis from Defective Drainage.—At a recent meeting of the Montreal Medico-Chirurgical Society DR. J. C. CAMERON endeavored to prove that when a number of cases of sore throat with adynamic symptoms break out in a household there is good reason to suspect defective drainage as the cause. He detailed ten cases which occurred in one house, in which an examination revealed a defect in the ventilation of the soil-pipe. In six of the reported cases both severe tonsillitis and ulceration, resembling that of diphtheria, were present.

Dr. Major, commenting upon this paper in the *Journal of Laryngology and Rhinology*, January, 1890, states his belief that defective drainage is frequently the cause of affections of the throat, both acute and chronic. In one instance coming under his observation, a family of five persons were attacked with painful symptoms referred to the throat. The appearance of the throat did not indicate acute inflammation, but the pharynx was covered with a thin, easily detached film. In each case the illness was ushered in with vomiting and slight elevation of temperature. The duration of the indisposition was only forty-eight hours. On examination of the drainage system the iron soil-pipe was found to have been recently broken at the outlet in the wall of the house, thus allowing the sewage to escape under the floor of the basement. Such a cause should always be suspected in the case of painful throats that defy the usual methods of treatment.

The Treatment of Nævus by Collodion.—At a recent meeting of the Midland Medical Society of England, MR. THOMAS showed three cases of nævi treated by the application of collodion—one in the back, another in the parotid region, and a third over the anterior fontanelle in a young infant. Collodion was painted over them and the skin in the vicinity, the applications being usually carried out by the mother. In all considerable improvement had resulted, rendering further treatment by operation unnecessary. He pointed out the absolute freedom from risk or danger, and the advantages it offered in some situations where almost all methods were unsafe.—*Birmingham Medical Review*, January, 1890.

Antiseptic Treatment of Erysipelas.—In the *Revista Clinica de los Hospitales*, December, 1889, an account is given by SENORES GANADO and DURÁN of a method which has proved highly successful in the hands of Dr. Huertas, of Madrid, in the treatment of erysipelas of the face. It consists of painting over the inflamed part with 1 : 1000 sublimate solution, followed by the application of a covering of carbolized cotton-wool; this is done twice in the twenty-four hours. In twenty cases thus treated the spread of the inflammatory process was at once checked, the zone of redness remaining exactly as it was when the case came under treatment, the disease entering on the desquamative stage on the second or third day. The authors claim that by this method the length both of the disease and of the period of convalescence was notably diminished, and that the complications frequently accompanying erysipelas were avoided. Constitutional treatment was at the same time not neglected, the *primæ viæ* being kept clear and tonics freely given. In the way of internal medication, however, most reliance seems to have been placed on the administration of Van Swieten's "liquor," a solution of corrosive sublimate in alcohol much used on the Continent. Even in cases which were admitted as late as the third or fourth day of the disease, the temperature was reduced, and the local condition speedily improved by this treatment.—*London Medical Recorder*, December 20, 1889.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

SCHOOL NEAR-SIGHT.

WIDELY and variously as the subject of myopia in the schools has been discussed, much remains indeterminate or contradictory, principally because of the diverse premises from which its students have started and the differing methods which they have employed; and although it is a question which concerns the Germans most especially, it is one in which every nation is really interested, since none are free from participation in it. A valuable contribution to the matter has recently been made by Professor v. Hippel, in Giessen. While reacting against the excessive outcry of some who regard the evil as ominously great and growing, v. Hippel is still among those seeking means for its prevention or diminution; and his study has special value because it deals with the practical endeavor to meet the requirements of relief, and with the results which have been thus obtained. The hygienic construction of the schoolhouse, with abundance of light and air, the subdivisions of the tasks of the day so as to afford intervals of rest and recreation, the enforcing of gymnastic exercise, the avoidance of overburdening the pupils with tasks in school, and especially with work to be done at home—these and many other matters insisted upon by the reformers would seem to have had an ideal realization in the new gymnasium of Giessen. When v. Hippel began his study of the eyes of its pupils in 1881, the new building of the gymnasium had been but two years in use, and most of the elder scholars probably showed the effects of their unsatisfactory surroundings in the old structure; only after 1883 were the improved methods of instruction in full operation, and only in 1889 had he to deal with pupils who had been through almost all of their school life under the present good hygienic conditions. A gradual lessening of the myopia in the school was, therefore, to be expected; and the result showed 27.6 per cent. in 1881, falling to 17 per cent. in 1889. This is more evident in the class percentages, which were in 1881, 0, 12.5, 15.5, 19, 36.4, 57.6, 36.7, 54.1 and 78.6; but in 1889, 1.3, 9.1, 9.5, 16.7, 21.7, 36, 21.4, 39.3 and 28.5. Myopia increased, then, from 8.5 per cent. in the lowest two to 67 per cent. in the highest two classes in 1881, from 5 per cent. to 34 per cent. in 1889. Most German gymnasia show proportions much less favorable; yet it must be noted that near-sight less than 1 D. has been left out of the count here, and would have decidedly raised the percentage.

The gain, though decided, may well seem unsatisfactory, and may appear to call in question the value of the hygienic reforms so ardently advocated in many quarters; but careful consideration of the matter will show that the limited gain is really of great importance. Thus a study of the effect of this growing near-sight upon the visual acuity of the pupils shows that in this school at least serious and irremediable decrease in vision is exceptional. With the aid of glasses few of the myopic eyes showed subnormal sharpness of sight; while the proportion and degree of such a lowered vision were greater among the hypermetropic and especially the astigmatic. Explanation of this last may be readily found in the circumstances of the investigation, and similar results would doubtless be found elsewhere. The favorable showing for the myopes of the Giessen gymnasium is in this respect probably paralleled by few of the German schools; and there is good reason to believe that its good hygiene deserves much of the credit.

Another side of the picture is shown by the history of the limited number of pupils who were followed through any considerable part of their gymnasium course. Only 44 were followed for nine years and 40 for eight years; these showed the development of myopia in 26.4 and 21.2 per cent., respectively, of the non-myopic eyes; and increase of the degree

of myopia took place in almost all of those previously myopic. How much of this may fairly be ascribed to the exacting work of the school, how much to heredity (of which evidence was obtained in about 50 per cent.), it is not possible to say; but one point incidentally given deserves careful consideration. In spite of warnings given by the examiner and reiterated by the teachers as to the injurious influence of improper glasses, and the pointing out and condemning of such when found, his last examination showed that but one-fourth of the myopes were wearing proper glasses, half of them were wearing none, although their use had been advised, while the remaining fourth had improper ones. In Philadelphia, where the multitude, especially of children, wearing glasses is rather striking and is apt to raise the question whether the prescribing of glasses by oculists is not overdone, it is noteworthy that cases of the "progressive myopia," so much noted abroad, are decidedly rare—thanks probably to the use of mydriatics and to scrupulous accuracy in the correcting of refraction errors.

The two conclusions which v. Hippel draws seem worthy of careful consideration:

"In spite of the best architectural construction and appropriate arrangement of a schoolhouse; in spite of the avoidance of all overburdening of the pupils, and in spite of regular medical supervision, a notable proportion of the pupils will become near-sighted during the school period, and the near-sight present will increase in another portion."

"By following correct hygienic principles in the external conditions of the school and in the organization of the instruction, the frequency of near-sight may be considerably diminished, its grade may in the great majority of cases be kept within moderate limits, and diminution of the sharpness of sight largely avoided, while the occurrence of the usual complications of myopia, staphyloma posticam and spasm of accommodation, will be less frequent than they are otherwise apt to be."

REVIEWS.

Estudios sobre Termometria Clinica. (Studies on Clinical Thermometry.) By Fernando Escovar, M.D. 8vo., pp. 55. Mexico: Ricardo Sainz, 1888.

Dr. Escovar has given in his little work a full account of clinical studies of the febrile changes of certain diseases, such as measles, typhoid fever, intermittent fever of the quotidian type, pneumonia, pyæmia, and erysipelas. Dr. Escovar does not pretend, in this part of his paper, to give or suggest anything new; he simply writes about his clinical observations, some of them being very interesting, and all, we may say, corroborative of those of other investigators. But the most interesting portion of his essay is the one in which he gives an account of the original studies he has made on the temperature of the neck of the uterus and vagina and of the male urethra in certain disorders of the genito-urinary apparatus.

He made 153 observations with regard to the temperature of the neck of the uterus and the vagina, and found that in 46 women, aged from twenty-eight to forty years, who suffered from simple hypertrophy of the neck of the uterus, the temperature at this place was identical with that of the vagina, namely, 37.5° C. In 22 cases of granular metritis of the neck, the local temperature was 37.4° C., and that of the vagina 37.3° C. In 28 cases of uterine catarrh the temperature of the neck was 37.3°; of the vagina, 37.2°. In 57 cases of atresia of the neck the temperature was 37.2° in vagina and uterus.

He also made 320 observations of the temperature of the male urethra as follows: In 145 cases of blenorrhœa and stricture, the thermometer marked at the region mentioned 36.1° C. In 92 cases of blenorrhagia, in the first period, the temperature of the urethra was 37.4°. In 82 adults, between thirty-five and forty-five years of age, who suffered from spermatorrhœa and impotence, the urethral temperature was 35.5°, and it is to be noticed that in 6 of these cases, who suffered at the same time from migraine, the thermometer only marked 34° C.

From these studies Dr. Escovar arrives at the following conclusions:

1. There is but little variation in the temperature of the male urethra, or of the neck of the uterus and vagina, in states of disease.

2. The pathological conditions under consideration do not influence, in any marked degree, normal temperature.

The pamphlet is interesting, especially as regards the latter part of Dr. Escovar's studies in a field which, so far as we know, no one has as yet worked carefully.

CORRESPONDENCE.

LISTER'S NEW DRESSING.

To the Editor of The Medical News,

Sir: A few weeks ago you published an abstract of a clinical lecture delivered at the University Hospital on "The Latest Listerian Method,"—the double cyanide dressing as used by Sir Joseph Lister—my remarks having been based on an experience of a few months. As a more extended use of the dressing still further convinced me of its great efficacy, and as I knew that Lister was constantly endeavoring to improve the details of his methods, I wrote him to ask if he had made any changes in this direction or in his method of preparing the gauze since he had explained them to me in July of last year. The accompanying letter which I have just received in reply should be read in conjunction with the papers in *The Lancet* to which he refers. It was not intended for publication, but I venture to send it to you (with the omission of a personal paragraph), as

I am sure all practical surgeons in this country are interested in knowing the most recent views on antiseptic methods of the man who has not only revolutionized the principles of wound treatment, but is now devoting himself with unremitting labor to the elaboration and perfection of its details. Yours truly,

J. WILLIAM WHITE.

1810 S. RITTENHOUSE SQUARE, PHILA

LYME REGIS, DORSET, January 7, 1890.

MY DEAR PROFESSOR WHITE: I have to ask your forgiveness for having so long delayed answering your inquiries regarding our antiseptic methods.

The papers which I have lately published on the cyanide dressing (see *The Lancet* of November 9, 1889, and January 4th of this year) will both supply the answer to some of your questions, and serve also to explain the difficulty I have had in finding time for correspondence. I felt it urgently incumbent upon me to publish the cyanide dressing; but, at the same time, I was very anxious to produce it in as useful a form as possible, and the labor connected with the successive improvements that suggested themselves was more than enough to occupy any spare time at my disposal. The preparation of the gauze will now present no difficulty if you obtain from Messrs. Morson, Southampton Row, London, W. C., the *dyed cyanide*, and follow the instructions given at the end of my second paper.

You will observe that the gauze, after being drawn through the liquid in which the cyanide is diffused, is hung up to drain until it ceases to drip, and then is placed in a folded sheet to remove the still redundant moisture. The precise time for which it remains in the sheet is a matter of no material moment; about half an hour being adequate to leave the gauze moist without being inconveniently wet. Immediately over the wound is placed a portion of the gauze, say about sixteen layers thick, washed in a solution of carbolic acid to get rid of the bichloride of mercury in the dressing in contact with the wound. I prefer for this purpose one part of carbolic acid to twenty of water, as safer than any weaker solution.

A very pure acid should be used, because, if impure, it is not completely dissolved, and the undissolved particles are needlessly irritating to the surgeon's hands. When you change a dressing you apply this piece of gauze over the wound before you proceed to clean surrounding parts with the carbolic lotion.

The carbolic acid soon flies off from the washed gauze, leaving nothing in it in contact with the wound but the unirritating cyanide.

By proceeding in this way I have not found it necessary to use "protective." As to the amount of unwashed gauze to be applied, that will depend upon the amount of discharge that you anticipate.

In the early stage of a wound, where you expect much sero-sanguineous oozing, it is desirable to use a considerable mass, say an inch in thickness, and extending well on all sides beyond the wound. Further, it is well, where free discharge may occur, to place over the dressing a piece of thin mackintosh with the caoutchouc side (antiseptically washed) next the dressing. This is for the purpose of preventing the discharge from coming directly through the dressing. It does not, of course, overlap the gauze, nor need it even extend to its edge. Where the part operated on is placed on a splint, as after resection of the knee, the padding of the splint is lined with such a piece of mackintosh.

It is unnecessary to purify bandages or elastic bands that are placed outside of dressings, but if a bandage is used in the interior of a dressing, as in bandaging a stump next the skin, it is purified sufficiently by soaking it thoroughly with a solution of corrosive sublimate 1 : 2000. For purifying the skin I use water containing both 1-20 part of carbolic acid and 1-500 part of corrosive sublimate (*i. e.*, both combined). Or, in private practice, I commonly first wash thoroughly with 1 : 20 carbolic acid solution, and follow it up by washing with 1 : 500 corrosive sublimate lotion.

The towels placed around about the seat of operation are wrung out of 1 : 2000 sublimate lotion, and this is also used for the sponges during the operation. At other times the sponges, after being well washed in water, are kept in 1 : 20 carbolic solution.

The carbolic solution is also used for purifying the instruments before an operation. At the end of an operation, before beginning to stitch, I generally wash the wound with 1 : 500 sublimate lotion, and irrigate with 1 : 4000 during the stitching.

But where I open into a joint, such as the knee, I avoid the use of the strong sublimate solution, which is seriously irritating to the synovial membrane; and in that case I have irrigation during the whole operation with 1 : 4000. As to rendering wounds aseptic which have been infected, that is, speaking generally, a thing on which you can never reckon; in recent wounds, like compound fractures, the chance of success is, of course, always greater the shorter the time that has elapsed after the infliction of the injury.

If the skin and wound are greasy, oil of turpentine is of great value for cleaning away the greasy dirt, and the use of a nail-brush with carbolic and sublimate solutions, after the turpentine (or without it if there be no special occasion for its use), is very valuable. In most cases where septic sinuses are present, it is simply hopeless to try to extirpate the septic mischief; but very great advantage is gained by washing the cut surfaces in an operation under such circumstances with solution of chloride of zinc, forty grains to the ounce of water. This is done once for all at the conclusion of the operation, and prevents putrefaction during the critical early days after the operation. The same solution is also used where the wound communicates with a septic cavity, as after the removal of a portion of the tongue, or of a jaw; and under these circumstances it is also useful to apply iodoform to the cut surface after the chloride. In cases in which the septically infected part is of very limited extent, as, for example, where a suppurating strumous gland has discharged without an antiseptic dressing, complete disinfection may often be obtained by applying undiluted liquid carbolic acid, after scraping away the degenerated gland (or other) tissue with a sharp spoon.

. . . . . Please accept my kind regards, and believe me Very sincerely yours.

JOSEPH LISTER.

Recent Mortality in New York.—It is stated that in one day there were thirty deaths in the New York hospitals that were certified to be due to epidemic influenza and its sequels.

NEWS ITEMS.

A Posthumous Essay of Volkmann's.—The Berlin correspondent of the *Lancet* states that Professor Richard von Volkmann left behind him, almost ready for the press, an essay on cancer, which will be published soon by Dr. Fedor Krause, who was his assistant for many years. Volkmann ordered in his will that none of the numerous other medical and poetical writings which he left behind him should be printed.

A Promotion.—Dr. Thomas D. Ingram, formerly of Philadelphia, has been promoted to the position of Medical Referee in the Bureau of Pensions, in the place of the late Dr. Charles Macmillan. Dr. Ingram has hitherto held the office of Assistant Medical Referee.

A German Society for the Study of Hypnotism.—A society, chiefly composed of physicians, has been organized at Berlin, Germany, for the cultivation of experimental psychology, but at present it is mainly devoted to the study of hypnotism, The society was established in January, 1888, and has for its Secretary Dr. Max Dessoir, of Berlin.

The Treatment of the Insane in Canada.—It is not generally known that Canada, as well as the United States, has suffered from the meddling of politicians in the treatment of the insane. The Montreal *Medical Journal* shows the unfortunate fact that in that country it is not the custom to appoint men to the position of superintendent because they are fitted for the work by education or experience: "In most of the provinces the first, and in fact the only, qualification is the reputation of being an energetic machine politician. To be a rejected parliamentary candidate is a qualification which rarely fails in securing the desired position." A position of this kind must presently be filled in Montreal, at the new Protestant Hospital for the Insane, and the Montreal *Journal* very properly enters its protest agatnst the appointment of any one who has not had a special training in psychiatry. That *Journal* also takes occasion to remind the medical profession that the insane of the Northwest Territories are housed, not in an asylum or hospital, but in the Manitoba Penitentiary. The duty of correcting this evil devolves in part upon the Canadian Medical Association, in that a strong statement of the case by that Association would, without doubt, impel the government to build an asylum in the Territories, or to have the insane intrusted to the Manitoba Asylum at Selkirk. This latter method was at one time satisfactorily employed, but the authorities of the two provinces could not continue in agreement as to the price that the one should pay the other for the board and treatment of their lunatics, and so those unfortunates were ordered to be lodged at a penal institution. Concerning the governmental system in the Province of Quebec, there is a steadfast adherence to the antiquated and pernicious system of hiring out the insane, and there is no prospect of a reformation during the present generation. The status of the popular ignorance and a corresponding lack of intelligence among the popular representatives maintain "the unrighteous method" in the same force and esteem as in generations that are past.

Sixty-one Years in Medical Practice.—The oldest living graduate of the Medical Department of the University of Pennsylvania is said to be Dr. I. L. Coffman, of Phœnixville, Pa., who has been practising medicine sixty-one years.

The Alumni of the Woman's Hospital of New York.—The annual meeting of the Alumni Association of the Woman's Hospital of New York, was held at the building of the Academy of Medicine on January 16th. Afterward, the Association was entertained at dinner at the Hotel Cambridge by Dr. B. McE. Emmet. Among the guests, not members of the Association, who were present, were Dr. Fordyce Barker, President of the Hospital Board; Dr. Keith, of Edinburgh, Scotland, and Dr. T. G. Thomas. The afternoon session was devoted to scientific work. In the evening, Dr. T. Addis Emmet gave a reception to the Association at his home.

The British Medical Association.—The fifty-eighth annual convention of the British Medical Association will be held at Birmingham, during the last week in August, under the presidency of Dr. Willoughby F. Wade, senior physician to the General Hospital of that city, The Town Hall, Queen's College, and Mason College have been secured for the purposes of the sessions. The local committee on entertainment have their plans already laid for numerous excursions, and the customary evening receptions and amusements for the members.

ORIGINAL LECTURES.

EPIDEMIC INFLUENZA OR CATARRHAL FEVER.

Abstract of a Clinical Lecture delivered at the Hospital of the University of Pennsylvania, January 16, 1890.

BY JAMES TYSON, M.D.,
PROFESSOR OF CLINICAL MEDICINE.

THE very general prevalence of an epidemic of influenza at this time, as well as the presence of numerous cases in our wards, renders appropriate some consideration of this disease. We are all familiar with sporadic cases characterized by coryza, watery eyes, pain in the brows, sometimes exceedingly severe, but generally relieved by a free purulent discharge from the nose, substituting the primary watery one. With these symptoms are often associated great muscular pain throughout the body, a certain amount of febrile movement, and sometimes cough. The whole attack lasts from three to five days, and is commonly called influenza, or "bad cold in the head." Now, what is the difference between this condition and the cases of epidemic influenza or catarrhal fever now prevailing? The same symptoms are found, with varying constancy and severity. More frequently, however, than in sporadic influenza do we have catarrhal symptoms of the respiratory passages involving the larynx, trachea, the bronchi, and, more rarely, the ultimate structure of the lungs as a pneumonia.

In the first place, epidemic influenza differs in being due to a specific cause, whereas the ordinary influenza is generally produced by exposure to cold, or by irritating matters reaching the seats involved. As the result of a specific cause the disease becomes at once "infectious." "Infectious" is a word which must be carefully distinguished from "contagious." You will remember that all contagious diseases are infectious, but not all infectious diseases are contagious. The idea of "contagion" involves that the specific cause should be derived from another person having the same disease as contrasted with "miasm," a specific cause which originates outside the organism. Now, although in consequence of the very rapid spread of epidemic influenza one is forced to ask whether it is not contagious, I am inclined with most others to place it in the second category of infectious diseases, the "miasmatic." Modern bacteriological studies have eliminated from a once long list of miasmatic diseases one after another, until malarial fever and, perhaps, yellow fever, are left alone, unless we add to the category influenza.

Beyond the somewhat fantastic ideas announced some time ago by Saulsbury, no claim of isolation has as yet been made for the germ of influenza. It is to be hoped that the abundant opportunity afforded by the prevailing epidemic will have been taken advantage of by bacteriologists, and some definite conclusions arrived at.

The course of the cases of influenza in the present epidemic may, in general, be characterized as mild, the apparently large number of serious cases being proportionately small. Some important facts have been added to our knowledge of the disease, or, at any rate, brought afresh to our minds. The experience of almost every one has shown that the victim who yields most promptly to the disease, and goes to bed, or, at least, houses himself, is almost sure to be well in three, four, or five days. It is possible, however, for one attacked to fight off the disease without losing a day's time. But woe unto him who fails in this attempt, and as the result of taking cold, or from other cause, is forced to give up. He is either compelled to take to his bed from extreme prostration, or he suffers a relapse of the symptoms of the respiratory organs, which may extend to any depths. The prostration associated with epidemic influenza, or, at least, the present epidemic, is something peculiar. The weakness is extreme, and the slightest effort at exertion, physical or mental, promptly convinces the victim of this. The duration of the weakness is apt to be prolonged unduly, a week, or even two weeks, being required to overcome it. The recurrent pulmonary symptoms, if confined to the larger air tubes, do not give serious trouble, but if the air vesicles become invaded, the case is much more grave. A pneumonia thus occurring, is apt to be ushered in with a chill, and extends rapidly to the whole of one lung, and even to both lungs. When a part of the primary attack the pneumonia is more apt to be catarrhal and circumscribed, creeping from the bronchi into the air vesicles, and is less serious, although it may also be fatal, particularly in old persons. More rarely the inflammation is confined to the fine bronchial tubes, and we have the physical signs of a capillary bronchitis.

Another symptom which requires consideration, is the temperature. It is not commonly very high at the beginning, although I have known it to be 106.2° at the first observation in a patient now convalescent in our wards. More frequently it does not exceed 103° at the highest, and is often but slightly above the normal. The patient alluded to had been walking about with the disease up to the time of his admission. During convalescence the temperature is apt to become subnormal, falling as low as 96°, and in this patient there was a fall in four days from 106.2° to 96°. The explanation of the lowered temperature can only be had on the ground of a lowered vitality, which is also responsible for the weakness.

Another important fact in connection with epidemic influenza is this, that its presence is apt to make more serious other diseases which may occur during its prevalence. This is especially true of pneumonia, instances of which are sometimes undoubtedly regarded as secondary to influenza, when they are really primary cases. That they are signally fatal, has been amply attested by

the numerous cases which have occurred recently among us.

The *treatment* in the majority of cases is very simple. Rest in bed, without medicine, answers for a large number. Beyond this the treatment is mainly symptomatic, antipyrin for the pains when present, and quinine to keep up the strength. In ordinary cases requiring such treatment, I am in the habit of giving five grains of antipyrin every four hours, alternating with two grains of quinine as often, omitting the former when the pain has disappeared, but continuing the quinine. When the pains are very severe the antipyrin may be given more frequently, and even in larger doses. I have found it necessary also to give as much as eighteen grains of quinine daily. The cough is admirably treated with turpentine stupes, and when there are positive laryngeal symptoms, "Dobell's solution" sprayed into the larynx is very useful. It may also be sprayed into the nasal passages, or cocaine may be similarly used. Where the cough is disturbing, I have found ammonium chloride in six-grain doses, with fifteen minims of syrup of squills, and two drachms of compound licorice mixture sufficient to answer the purpose. Opium may be given in large doses if required. For the prostration, supporting measures are necessary, and even stimulants may be called for. The entire absence of appetite, and the complaint that all things taste alike, are to be ignored, and the patient must be forced to take food, which must be made as attractive as possible.

What shall we do for the pneumonia which becomes often so grave a complication? In a few cases it is a true "pneumonia fulminans"—strikes the patient down so suddenly and violently as to make all treatment unavailing. In other cases the physician reaches the patient when the disease is so advanced that depleting treatment of any kind is contra-indicated by weakness. Whether a bleeding immediately after the violent chill—even before the physical signs of a pneumonia have manifested themselves—would be of service, I have not had the opportunity of determining; but I am sure that some of my country friends would say that to omit it would be culpable. All depleting measures should be restricted to the first or, at the latest, to the beginning of the second stage of pneumonia where there are engorged vessels and more or less patulous air-vesicles. In the second stage the bloodvessels are already beginning to be compressed, and with the establishment of the second stage the lung is nearly anæmic, the distended air-vesicles compressing the bloodvessels through which the heart is trying to pump the blood. In the first stage, too, when the pulse is full and strong, veratrum viride may be used, as it quiets the heart, while it opens up the capillaries throughout the system and allows the lungs to empty themselves of the surplus blood. To use the expression of my colleague, Dr. Wood, concerning veratrum viride, you bleed the patient into his own abdominal vessels, and thus depress, while you do not exhaust him. In the second and third stages stimulants are indicated, and especially digitalis in full doses, to aid the heart in its difficult work. This should be given in doses sufficient to affect the pulse, and this effect should be kept up. Dry cupping and blistering are, in my judgment, never out of place in pneumonia, for they can do no harm, if they do no good. They should be followed by a jacket of wool, by which warmth and uniform temperature are kept up.

Beyond this there is little to be done, although an emergency may be tided over by the hypodermic use of digitalis, or of the same drug combined with ether. Under such circumstances fifteen minims of tincture of digitalis may be drawn into the syringe and the rest of the barrel filled with ether, and the mixture injected. Both may be repeated separately or conjointly.

Let me say to you, in conclusion, that one need not wait for the physical signs of a pneumonia to present themselves before beginning the treatment. Given a chill after exposure, with no other cause to explain it, and you may consider a pneumonia as almost inevitable. Oftentimes a pneumonic focus in the centre of a lung does not furnish any physical signs, while to wait until it approaches the surface causes a delay in the treatment which may be fatal.

A rarer complication of epidemic influenza than pneumonia—one, however, which our wards illustrate in a typical manner at present—is pericarditis. Our patient, a man of thirty-eight, had a simple attack of influenza, from which he was decidedly convalescent, when suddenly there appeared, coincident with a rise in temperature from 99° to 101.2°, an evident pericardial friction murmur, to and fro, rough, rasping, and superficial in character, loudest to the left of the mid-sternal line, but loud also at the apex. It was not heard at the base, nor conducted into the axilla. There was evident enlargement of the cardiac area of dulness. A blister was applied, and the next morning the sound had already grown less loud. There was also some pleurisy in the same case. The termination is not always so favorable. A case has occurred in one of our hospitals in which the pericardium was tapped, a purulent fluid removed, and a drainage tube inserted.

ORIGINAL ARTICLES.

A FAILURE IN BRAIN SURGERY.

By HAL C. WYMAN, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY IN THE MICHIGAN COLLEGE OF MEDICINE AND SURGERY, DETROIT.

JAMES H., a rugged and robust young farmer; father of one child. About a year ago, while digging in the field, he was suddenly attacked with pain in the back of the head. At first supposing it to be merely an ordinary headache, he went to the house and bathed his head with cold water, but the pain continuing severe, he consulted a physician four miles distant, returned home, took the medicine as directed, and was considerably relieved of his suffering. The following day he did not feel strong enough to work, and sent for the physician, who diagnosed malarial fever. The attack lasted about six weeks, during which time he suffered more or less from pain in the head. Becoming dissatisfied with his medical attendant, he sought other advice, which confirmed the original diagnosis of malaria. He took many drugs, but experienced no marked relief from the pain. About four months after the beginning of the attack, he found that his eyesight was failing. He also suffered from nausea and his sleep was disturbed. He vomited a great deal, although the

attacks of vomiting would not come on until some time after taking food, so that he did not lose flesh rapidly. Pain in the frontal region continued persistently. He was then placed upon potassium iodide. This drug for a time seemed to make some impression on his sufferings, and under its influence he was able to secure a few hours' sleep. However, after a few days its effects passed entirely away, and the pain returned with renewed vigor and intensity. He became still more restless and sleepless, vomited more frequently, the symptoms finally culminating in an epileptic seizure. Following this attack of epilepsy, he had divergent squint and additional convulsions, with marked muscular weakness and some fever.

Drugs of every sort were tried in vain, the pain continuing.

Dr. Mere, at my request, made an ophthalmoscopic examination of the eyes and found the condition of the retina indicating pressure upon the optic tract.

Operation.—The man became blind or partially blind within a few weeks after the attack of headache. He had had almost no unilateral symptoms, and had but slight movements of rotation, and at times great muscular weakness. These facts led me to locate the disease in the neighborhood of the sella Turcica and in the cerebral ventricle. Therefore, I trephined the frontal bone just above the supra-orbital ridge on the right side. One button of bone was removed, and through the opening the membranes were incised. First, however, the dura mater was raised and a probe pushed along the orbital plate of the frontal bone in the direction of the optic commissure. Then the finger was introduced and the parts carefully explored, but no tumor or abnormality being detected, a small director was pushed cautiously through the anterior lobe of the right cerebrum in the direction of the anterior horn of the right lateral ventricle. But little fluid was evacuated, owing to the brain-substance choking up the instrument. No sensation as of the point of the director free in a cavity was observed. During the administration of the anæsthetic the patient nearly died from failure of respiration. His respiration resembled the Cheyne-Stokes respiration in that his breathing was at times very rapid and then slow. The opening was made at the position designated because the symptoms pointed to disease in the neighborhood of the optic commissure and crura cerebri, and to effusion into the ventricles. A brief recapitulation of the morbid phenomena presented by the case may serve to make clearer my reasons for operating. Pain, quite uniform in quantity and character; fever, of several weeks' duration, immediately after the attack of pain; impairment of sight in both eyes, varying at times in degree; nausea; movements of rotation quite indistinct in the history; general impairment of strength not unilateral. No incoördination; disturbance of sleep variable; copious nasal discharge and impairment of sense of smell. These led me to think that there was effusion into the ventricles, with disease near the optic commissure and crura cerebri which might be removed by an operation of the kind described. The operation was made in the amphitheatre of the Detroit Emergency Hospital in the presence of the students of the Michigan College of Medicine. Thorough cleanliness was observed in every detail of the work, and the autopsy revealed no evidences of wound infection.

Autopsy.—Body moderately emaciated. Wound crescent-shaped on right forehead beginning near the external angle of the orbit, ranging upward and toward the median line of the face until the root of the scalp is reached, then descending to a point midway between the eyebrows. It was closed with nine interrupted sutures and had a plastic exudate between its surfaces.

The general appearance of the body suggested a man of moderately strong physique. His head was well shaped. On removing the calvarium the dura mater was adherent by numerous Pacchionian bodies which had in several places almost perforated the bone. A wound about three-fourths of an inch in length was found in the dura mater over the anterior lobe of the right hemisphere, which corresponded to a hole in the right frontal bone made by the crown of a trephine. Incising the dura and the attachment of the falx cerebri to the crista galli, they were turned back so that the arachnoid and pia mater were exposed. Much fluid was present in the subarachnoid space. There was some ecchymosis of the arachnoid and pia mater near where the dura mater had been divided at the time the bone was trephined. There were also present on the surface of the pia some particles of brain-tissue about the size of grains of wheat.

The membranes were entirely removed, and with a sharp knife a section was made through the right cerebrum on a level with the corpus callosum. This opened the right cerebral ventricle and allowed several ounces of fluid to escape. The left ventricle was opened in the same way, and was found distended with fluid. The third ventricle was then opened by cutting through the corpus callosum and fornix, and was found distended with fluid. The *iter e tertio ad quartum ventriculum* was distended with fluid, so that it easily admitted a lead-pencil into the fourth ventricle. No other changes in the cerebrum were observed, except the shallowness of the spaces between the convolutions. The membranes were now removed and the cerebrum turned back to expose the optic commissure and the tentorium cerebelli, which was divided so that the crura cerebri, pons Varolii, and medulla oblongata could be easily examined. Nothing abnormal was

noticed, except the excess of cerebro-spinal fluid. The optic nerves and commissure were normal. The spinal cord was divided after cutting the cranial nerves, and the entire brain was turned out of the skull. The cerebellum, pons, and medulla appeared normal at first, but looking more carefully at the cerebellum that organ was found to differ markedly in the appearance of its right and left hemispheres. The left hemisphere had a swollen appearance and a peculiar elastic feel which did not exist in the right hemisphere. A cut was made into it to demonstrate the arbor vitæ, when about an ounce of fluid ran out. Separating the cut surfaces, a cavity was found to have been divided which measured one-half inch in one diameter and one inch in another. Within this cavity, which was walled entirely with medullary matter, not a point or streak of gray showing at any point, a tumor oval in shape was found. It was about three-fourths of an inch in its long diameter, and was attached to one side of the cavity by a thick, short pedicle.

REMARKS UPON EMPYEMA.[1]

By MARY PUTNAM JACOBI, M.D.,
of New York.

(Continued from page 122.)

The little boy, whose case forms the text of this paper, as soon as the diagnosis of empyema had been confirmed by the hypodermic syringe, was etherized, laid upon the affected side, and an incision made in the eighth intercostal space in the posterior axillary line. The operation was rendered a little more difficult by the position given to the child. But this inconvenience was held to be compensated by the advantage of securing to the sound lung entire freedom from compression. The incision through the skin was a little less than an inch in length, and was made layer by layer until the pleura was nearly reached, when a trocar was plunged in, and its opening subsequently enlarged until it would admit a drainage-tube the size of my finger. This could just be squeezed through the space between the ribs, which, as always in a young child, was narrow.

On account of this narrowness, which has frequently been recognized as a source of difficulty, it did not seem that anything would be gained by making a longer incision, unless, as in Dr. Cabot's method, two drainage-tubes were to be inserted.

The size of the opening which should be made in the chest, in order to evacuate a purulent effusion, has been the subject of animated controversy.

It seems scarcely necessary to reopen the discussion in regard to aspiration of the chest in empyema. The discussion of the New York Academy of Medicine, held in 1887, resulted in the unequivocal condemnation of aspiration for purulent effusion, and in the recommendation of antiseptic incision as a method which, as Dr. Holt remarked, has changed empyema in children from being one of the most fatal to one of the most amenable of diseases. But it is both interesting and surprising to note how very recently this method has been definitely acquired. Guibert, in 1875,[1] relates with complacency the case of a boy of eleven, under treatment for nine months, and subjected to seventy-four punctures with Dieulafoy's aspirator. In 1862 Ziemssen, quoted by Schenks, said that operation was rarely needed for empyema in children. In the great majority of cases in which aspiration has been tried, the continued recurrence and aggravation of all morbid conditions decided the physicians to resort to incision, with drainage. Dr. Holt has collected 121 cases treated by aspiration, of which 6 died; 23, or nineteen per cent., were cured; the rest came to treatment by incision. Yet in the International Congress of 1881, although Ranke and Gerhardt advocated free incision, Baginsky advised delay, to see if the pus might not be removed by expectoration. Robert Lee and Parker, of London, advocated repeated aspiration, and Dr. Jacobi reported three cases of empyema in children, observed in one year, who had been radically cured by aspiration.[2]

Some years ago I treated by aspiration a case of empyema in a child of eighteen months, and the child died.[3] The dangers of aspiration are not

[1] Read before the New York Academy of Medicine, Section on Pædiatrics, November, 1889.

[1] Lyon Médical, November, 1875, quoted by Bouveret.

[2] Esch, N. Y. Med. Record, 1887, relates a case of empyema in a boy eight years old. Twelve ounces of pus were withdrawn from the pleura by aspiration, and, after a temporary improvement, the refilling of the chest necessitated repetition of the aspiration seven times in the course of a few weeks. Each time, eight to fourteen ounces of pus were withdrawn. The child had chills, and a temperature ranging from 102° to 104°. Finally, Esch injected through the aspirating needle eight ounces of a two per cent. solution of biborate of soda, and withdrew in ten minutes. Speedy recovery.

Leichtenstern, in Gerhardt's Cyclopædia, says that it is unquestionable that empyema *may* be cured by repeated puncture and aspiration, like any other abscess. In 1871, Bouchert (Gaz. des Hôp., 1871) proposed to treat infantile empyema exclusively by this method.

Branthomme's thesis contains eighteen cases cured by single aspiration.

Bouveret quotes forty-three from the thesis of Branthomme, divided into four groups. In the first group of 18 cases, a single aspiration sufficed to cure. In the second group of 11 cases, the aspiration was practised twice—the recovery equally prompt. In the third group of 3 cases, there were three aspirations, and speedy recovery. Finally, in a fourth group of 11 cases the number of aspirations ranged from 6 to 122.

[3] Schenker (Jahrb. für kinderheilk., N. F., 1883, Bd. xx.) relates fifteen cases, of which six were treated at first by aspiration. Of these one died after a second aspiration. The others were treated by incision and drainage.

Goodhart (Guy's Hosp. Rep., 1877) reports two cases of aspiration, both of whom died.

purely negative and dependent on delay in relieving the organism of its collection of pus, and lungs and heart of the mechanical impediments offered to their functions; but, unless the disinfection of the aspirating needle is perfect, and it often is not, there is the same danger in plunging it into a closed pleural effusion as has been so often noted in the hypodermic exploration or aspiration of abdominal cysts, and of which I have myself reported two observations. If germs are carried into a cavity with a free opening, and from which a current of fluid is constantly flowing, they have at least a large proportion of chances of being washed away. But, introduced into an hermetically closed cavity, no such chance is offered, and infection is unavoidable. This danger does not seem to have been emphasized by authorities as distinctly as the fact of the almost inevitable recurrence of the effusion after the most complete aspiration, and the great probability that the aspiration in every case must remain incomplete. Other more exceptional dangers of aspiration, empyema shares in common with serous effusions; the dangers of albuminous expectoration, pulmonary œdema, and other accidents liable to occur when a lung, bound down by adhesions, is drawn upon by a powerful aspirating machine. These dangers are, of course, more rare in children, precisely because in them the lung is usually movable. The prejudice in favor of aspiration dates from the epoch when incisions were made without any antiseptic precautions. We now know that many of the dangers then attributed to the introduction of air were really due to infection of the wound or of the suppurating cavity. But it is again surprising how recent is this discovery, and indeed how long a time elapsed after the establishment of the Lister method elsewhere, before it was applied to the treatment of empyema: according to Bouveret,[1] the very first case in which pleurotomy was performed for empyema with antiseptic precautions occurred in Calcutta, under the care of an English surgeon, Ewart, and was reported by him in 1873.[2] In 1877, Goodhart speaks despairingly of the conflict of opinion in regard to the treatment of empyema; says that the incision treatment gives a mortality of 33 per cent., and is not more favorable than Playfair's method of subaqueous drainage. "This," he observes, "is simplicity itself, and looks, at first sight, almost perfect. I do not know that even now I am prepared to say that any other method of treating empyema is better, but, after treating several cases and seeing others treated, I think if no other treatment can be made to give better results than it, empyema will remain a most fatal disease, with the chances for or against the patient's life about even."[3]

[1] Traité de l'Empyème, 1888, Paris et Lyon.
[2] Lancet, 1873. [3] Loc. cit.

In 1880, Dr. Cabot commented on the slow progress made by the antiseptic method in regard to the treatment of empyema, and attributed it in part to the tenacious belief of physicians that in aspiration they have a means of curing the patient with less risk, hence do not trouble themselves to master the methods by which incision may be stripped of its risks. At this date Dr. Cabot could find reports of but ten cases treated antiseptically, all in German; namely, four by Wagner,[1] four by Goeschel,[2] and two by Krabbel.

To-day, the cases of antiseptic pleurotomy have multiplied so considerably, that it would be useless to quote them in a paper like the present. I will again, therefore, simply refer to Dr. Holt's statistics of 63 cases, with 61 recoveries and 2 deaths. The statistics of Cabot and Eddison, reproduced in 1888 by Bouveret, of 40 cases of non-tuberculous empyema in adults, give 34 complete cures, 2 permanent fistulæ and 4 deaths.[3] The case which forms the basis of this paper is the sixth I have treated, and with success. My friend Dr. Annie Daniel also reports six cases where antiseptic drainage treatment was followed by complete recovery. There can be no doubt, therefore, that the pendulum of chances has swung over so considerably during the last decade, that, with incision and drainage treatment, recovery of children from empyema should be considered the rule—death the exception.

There are, however, four details of the treatment that are not so well settled. These are, the use of the spray, the size of the opening to be made in the chest wall, if puncture and aspiration be excluded; the employment of irrigations, and the use of a valve in the dressing. When, in 1873, far away in Calcutta, the antiseptic method was, as it would appear, first applied to the empyema operation, the incision and subsequent dressings were rigorously guarded by the spray. For a long time the spray was considered indispensable; and as late as 1888, Bouveret, while admitting the superfluity of the spray for other surgical operations, insists upon re-

[1] Volkmann's klinische Sammlung, No. 197. Also Berlin. klin. Wochen., 1878.
[2] Berlin. klin. Wochen., 1878.
[3] Among reported cases of successful pleurotomy may be cited:
Goeschel: Loc. cit., four cases, four recoveries (young children).
Phelps (N. Y. Record, 1880): fourteen mixed cases, eleven recoveries, three deaths.
Lindner: Jahrb. für kinderkrank., N. F., Bd. xvii., one case recovered—seven months' child.
Skerritt (Brit. Med. Journ., 1876): one case, recovered.
Cabot (N. Y. Med. Journ., 1880): seven cases, children, all recovered rapidly.
Redenbacher (Deutsch. Archiv. für klin. Medicin. Bd. ix.): one case, recovery in fourteen days.
Huber (Archives of Pediatrics, Nov. 1889): two cases, double empyema, recovery.

taining it in treatment of empyema. The spray was used by Skerritt[1] in 1876, by Koenig and Wagner in 1878,[2] but the latter does not consider it necessary, and the former claims always to resect a rib. The spray is uniformly advised by Douglas Powell,[3] and by Bennett in Ashhurst's *Cyclopædia of Surgery*. It was strenuously insisted upon by Dr. Cabot in 1880,[4] by Leamoine in 1880, and is advised by Donaldson, writing in Pepper's *System of Medicine*, whenever an incision is made six centimetres long. It is considered superfluous if the incision only passes through the skin and muscles, and the pleura itself is opened by a trocar. In the Academy discussion of 1887, Dr. Abbe advised the spray, but this was not mentioned by any other speaker, nor in the discussion at Washington last September over Dr. Huber's two remarkable cases of double empyema. Dr. Gerster, in his treatise on antiseptic surgery, expressly condemns the spray as an objectionable feature for empyema as for other operations.

In the case of the little boy here described, no spray was used, and recovery was complete—*i. e.*, the tube was withdrawn on the thirty-second day. In my five other cases, however, the duration of treatment was about two months. In Dr. Daniel's six cases the spray was also omitted, but other antiseptic precautions were used. The trocar and drainage-tube employed had been kept in pure carbolic acid during the twenty-four hours preceding the operation.

Of these six cases one died suddenly on the third day, twenty-four hours after an erysipelatous inflammation around the wound had been noted. In the five other cases the tube was removed on the thirteenth, nineteenth, twenty-third, twenty-eighth, and thirty-third days respectively.

While the fluid is running out from the incised chest no air can enter. The entrance of air is signalized by a loud suction noise, and takes place at the moment that the abnormal positive tension in the pleural cavity, due to the presence of the fluid, is changed to a negative tension by its evacuation. It is quite possible, if the contents be perfectly fluid, to place a thick layer of antiseptic gauze over the opening at the moment the flow begins to slacken. By this means any air drawn into the chest will be filtered. This would even be possible when, through a large opening, semi-solid masses of fibrin and clots were being being expelled by coughing.

It is generally admitted now that infection of wounds does not proceed from germs floating in the air, but attached to instruments and other solid bodies. Further, the experiments of Stimson, confirmed by Cabot himself, who so strenuously recommends the spray, show that air which has passed through spray continues to infect culture tubes; on the other hand, methods of operation which effectually exclude air, as the subaqueous drainage, and the guarded trocar of Reybaud, were very often followed by fever and other signs of sepsis, often fatal. On one day when I operated by the trocar on a child at the Mount Sinai Dispensary, another child of the same age was admitted to the wards and submitted to subaqueous drainage. The dispensary case, though brought from a distance three times a week, recovered, after some vicissitudes, in two months. The hospital case died of exhaustion after three.

In cases where air has been thoroughly excluded from the pleura opportunity remains for infection of the external wound; and this opportunity recurs with every change of the dressings. Constant irrigation of the lips of the wound during the dressing is a much more potent method of averting infection than is the spray.

The size of the incision seems to have been regulated according as the operators were more preoccupied with freeing the pleural cavity from pus, or with facilitating the reëxpansion of the collapsed lung. It is under the influence of the first idea that König and Demme have advised the resection of a rib for, at least, all adult cases; that directions are given for incisions six centimetres long, and that stress is laid upon placing the incision as low as possible. Certainly, for children at least, too many cases are now on record of cure by simple incision to allow us to consider resection as anything but an exceptional expedient. Further, so long as the contents of the pleura are entirely fluid, it is difficult to see why they will be evacuated any more easily through an opening of six centimetres than through a tube the thickness of a finger. The tube is only inadequate if there are solid coagula too large to pass easily through it. Similarly, it seems to me extremely doubtful whether the situation of the tube at a lower portion of the chest is more favorable to the outflow than a higher position. In a case of empyema that I saw in consultation with Dr. Daniel, the pointing was under the right clavicle, and here the opening was made. Drainage was perfect; and this is always the experience with spontaneous openings of empyema. The fact that these openings occur in the upper parts of the chest at least as often as lower down, is itself a proof that the contents of the pleural cavity may be pushed toward any point on the circumference, and do not follow the laws of gravity. The familiar experience of the straight glass drainage-tube which is so often plunged into

[3] Diseases of Lungs and Pleura.

[4] N. Y. Med. Journ., 1880. See also Neurbe-Fraentzel, in Ziemssen.

The spray was used in all the forty-one cases, including fourteen cases of children, in the statistics compiled by Bouveret.

the peritoneal cavity after laparotomy operations, shows that the pressure of the closed cavities of the living body is capable of forcing fluids upward as well as downward. In the empyema operations the perforated drainage-tube generally passes upward; it certainly did so in the case of Frank. But the circumstance did in nowise interfere with the drainage.

The forces which expel the fluid from the pleura are: 1. The positive tension existing in the cavity, and which, to the great detriment of the patient, has replaced the negative tension which is normal. 2. The reëxpansion of the lung, which should begin as soon as this positive tension is lessened. This is illustrated in the balloon and flask. 3. The respiratory movements—those of inspiration as well as those of expiration. During inspiration, when the chest-wall moves outward and enlarges the pleural cavity, all the contents of the cavity must move forward in the direction of the least resistance. Unless the opening be occluded, the lung will not so move, because the internal atmospheric pressure which should keep out the walls of its cavities, is neutralized by air on the other side, and is, therefore, inoperative. But if there be fluid in the cavity, its pressure exceeds both that of the air within and of the air without; and when compelled to move, it moves forward toward the point of least resistance—*i. e.*, the fistulous opening toward the external air.

For these reasons it is difficult to see any advantage in a very large opening; provided, of course, that the flow of liquid continues perfectly unobstructed.

The gradual contraction of the pus cavity, effected through the approximation of the pleural surfaces, can hardly be counted among the expelling forces. Certainly a most important condition for the formation of such adhesion is the persistent evacuation of the pus as fast as it forms. In the case of Frank, as the flow of pus through the canula began to slacken, an antiseptic pad was laid over the opening—not, however, before air was twice drawn into the pleura with the usual suction noise. The respiration was considerably accelerated at the moment of opening the pleura, and for some moments afterward, the inspiration becoming deeper. The same change in respirations is observed when a closed tube, communicating only with a manometer, is plunged into the healthy pleura of a dog. The change seems due entirely to the greater exertions made by the sound lung, but implies a direct transmission of impressions from the wounded pleura to the inspiratory centre in the medulla.

In the boy Frank the opening made by the trocar was enlarged by the bistoury until it would easily admit the drainage-tube; this was inserted, and secured by a safety-pin packed around with iodoform gauze, after the lips of the wound had been thickly powdered with iodoform, and while the pus was still running from the tube, an antiseptic dressing was applied without previous irrigation of the pleural cavity.

The question of irrigations into the pus cavity—primary or consecutive—has been strenuously debated. When advised, it is with the intention: 1. Of thoroughly removing all pus from the pleura, so that none may remain to decompose. 2. Of disinfecting the pleural cavity of germs which, in spite of all previous precautions, may have been carried into it.

Now this second reason can have no weight, if the antiseptic precautions previously taken have any real efficiency. As to the first reason, the records of cases prove that pus reaccumulates in the twenty-four or forty-eight hours following the operation in amount sufficient to necessitate a change of the dressings, and this, whether irrigation has been practised or not. Nevertheless, many of the writers who use primary irrigation, as Cabot, do not repeat the washing on account of this reaccumulation, but simply renew the dressings. If the irrigation be not needed the second time, it is difficult to see why, for the purpose of removing the pus, it should be required the first time.

The amount of pus that is poured out in the first day or two after the operation is often astonishing. In the case of Frank—where, at the first dressing, thick layers of cotton wool were used instead of, as subsequently, oakum—the dressing, clothes and even bedding were saturated. It is true the evacuation of pus had not been quite complete at the operation; but there could not have been much fluid in the pleura, for, before applying the dressing, I ascertained that almost normal percussion resonance extended all over the back of the chest. The abundant discharge, therefore, of the first day must have been due to a new formation or effusion of pus; and it is comprehensible that the removal of pressure from the pleural surfaces may facilitate an abundant emigration of leucocytes from the distended capillaries and lymph spaces of the pleural tissue.

In a perfectly normal progress of events, when the later or secondary elimination has been effected, the discharge from the drainage-tube should rapidly diminish and cease. Bouveret relates one case of complete cure in nine days, the shortest on record. Many cases are on record where the tube could be removed in twenty or fifteen days, or even less. In Ewart's pioneer case, an adult, the discharge is said to have become serous in six days. Two circumstances thwart this normal progress: the suppurating surface may become infected, or the pleural inflammation which gave rise to the suppuration may persist as suppurative, instead of retrograd-

ing to an adhesive form. In either case, the child will have fever, and the discharge will remain offensive. In either case, irrigation becomes indicated, and, if practised, will be followed by a fall of temperature.

It is certain that thousands of irrigations have been practised which only serve to keep up the irritation they were intended to allay. This is especially the case with carbolic acid irrigation, of either one, two, or three per cent. The danger of poisoning is very considerable; but, apart from that, the danger of irritating the inflamed tissue of the pleura is more uniformly present. Cases treated by carbolic acid irrigation have been described complacently as sustaining a treatment of three months, which, in a non-complicated case, itself impugns the treatment. In two of my own cases, one per cent. solution of carbolic acid was used for irrigation when the temperature rose; but the child became restless, as from pain, and the temperature rose higher. Irrigation with a solution of bichloride 1 : 6000 was substituted, and the temperature fell, not again to rise.

Out of the five cases reported by Dr. Daniel only one was irrigated. The irrigation was made daily with a two per cent. solution of carbolic acid, for a period of nineteen days, yet the fever continued with little abatement. It is evident that, apart from the irritation of the inflamed pleura, repeated irrigations tend to thwart the two essential parts of the healing process. Each tends to break down the delicate adhesions forming between the pleura, and to oppose the reëxpansion of the lung. No one can deny their utility when pus is found fœtid at the time of the operation, or if it become so afterward, for it is important to remove fetid pus or gangrenous masses at once, and not trust to their gradual elimination. But there is no proof that it is important to remove fluid and laudable pus at once, but only to provide for its free, steady, and uninterrupted gradual evacuation. As soon as the internal tension of the pleural cavity has been relieved by removal of such excess of fluid as spurts with force through the drainage-tube, and as soon as drainage is instituted and maintained, tendencies to absorption of pus are arrested and the lung is enabled to reexpand. If the pleural cavity were empty of fluid, but, from imperfect collapse of its walls, filled with air at ordinary atmospheric pressure, expansion of the lung would be retarded as much as in the presence of fluid. This is sufficiently demonstrated by the accident of pneumothorax. There is really no advantage in removing the pus faster than the lung can follow its retreat, and the contact of the pleural surfaces be effected.

In my case, no irrigation was made at the time of the operation. The next day, the rectal temperature, which had been 104° on the afternoon of the operation, had fallen to normal; the dressings were saturated, and were removed. During removal, air was twice, but only twice, sucked into the pleura. During the next week I did not see the child, but the dressings were changed every two days by another physician. The temperature, taken in the mouth, was reported as normal during the week, but the cough was severe, while it had been scarcely perceptible before. On the seventh day I saw the child again, and found the rectal temperature 101½°. The percussion resonance over the lung was nearly normal, the breath sounds harsh and bronchial without vesicular murmur; the heart was in place. In changing the dressing this time, the cotton wool outside the antiseptic gauze was replaced by oakum. Before replacing the dressing, air was again drawn into the chest with a loud noise. Again I did not see the child for four days, during which, however, the dressing was twice changed by the other physician. On the eleventh day after the operation, I found the rectal temperature 103°, the child coughing much, still pale and languid, complaining much of pain in the chest. On this occasion, and for the first time, I irrigated from a fountain syringe with a warm solution of corrosive sublimate, containing 1 : 6000. On this occasion, no air was drawn into the chest. Two other changes were also made in the treatment: a valve of rubber tissue, hitherto imperfectly applied, was accurately adjusted over the fistula, and antipyrin was given in five-grain doses every three hours. Three effects were observed: The temperature fell permanently after seven doses of the antipyrin had been taken. The discharge lessened so much that the dressing remained untouched for a week, and was then found scarcely soiled. The cough lessened, the child became lively and free from pain, and a week after the irrigation, eighteen days after the operation, was found running about, eating well, and appearing quite well. The dressing was replaced, left a week longer, when the fistula was found to be granulating abundantly, the discharge entirely trivial. It is possible that the tube might then have been removed; it was evident that the pleural cavity had contracted to a sinus around the tube. For greater security, the tube was simply shortened, and only entirely removed a week later, on the thirty-second day after the operation. The fistula closed immediately.

On the eleventh day, when irrigation was performed, the character of the discharge had changed—become slightly sanious, with a few small fibrinous coagula. But there was no evidence of their decomposition, nor of septic infection of the wound, although on several occasions the dressings had been too loosely applied, and the antisepsis imperfect. The fever, pain, and cough seemed to have been

kept up by the continued inflammation of the pleura, and it is this which seemed to subside promptly under the combined influence of the bichloride irrigation. the valve, and the antipyrin.

(To be concluded.)

HERPES PROGENITALIS.[1]

BY G. FRANK LYDSTON, M.D.,
OF CHICAGO, ILL.

HERPES progenitalis is an important, though relatively harmless, disease. Its importance depends chiefly upon its frequent occurrence. the greater or less amount of local irritation which it sometimes produces, and its demoralizing effect upon the mind of the patient. As is well known, it consists of a development of small vesicles filled with a watery, sometimes sero-purulent, fluid upon the skin or mucous membrane of the genitals. It is rarely seen in the female, although in Hebra's *Atlas* there is an excellent representation of the disease as occurring in a woman. According to Unna, the disease is not so very infrequent in women—this accords with my own experience.[2] Dr. Duhring states that he has never seen a single case in women. It is possible, as Unna says, that women are as susceptible to herpes as men, and if this be true, the reason for its apparent rarity must be the protected situation of the lesions which prevents their being readily discovered.

According to Legendre, Fournier. and Bruno, the coincidence of an herpetic eruption with menstruation is by no means infrequent, and in some women it comes on two or three days prior to each menstrual epoch. My experience is limited to a single case in which a lady suffers considerably at each menstrual period from a crop of herpetic vesicles and ulcerations about the inferior commissure of the vulva. They are very annoying from the pain and smarting which attend them, the act of urination being particularly distressing. With some attacks there occurs marked œdema of the genitals.[3]

The diagnosis of herpes progenitalis is, in uncomplicated cases, comparatively easy. There is in most cases a history of recurrent crops of vesicles and minute ulcerations perhaps independent of sexual intercourse. There will be no definite relation in the large proportion of cases to any particular act of intercourse—even when due to irritating materials deposited upon the mucous membrane during uncleanly coition the affection follows at variable intervals, in some instances the eruption appearing within a day or two, and in others not until the lapse of as many weeks. When the lesions have become ulcerated a diagnosis is often difficult.

The cause of herpes is usually said to be local irritation, but I am convinced, from personal observation, that by far the greater majority of cases are dependent upon a neurosis—the disease in this respect strongly resembling herpes zoster. Some patients of a highly irritable, nervous temperament, who are readily subject to nervous depression, and who perhaps suffer from more or less general debility, are affected at variable intervals with successive attacks. Malarial infection may produce herpes progenitalis as well as herpes in other situations. Unna is inclined to regard the disease as a rudimentary form of herpes zoster, and calls attention to the limitation of herpes zoster and herpes progenitalis to the peripheral points of distribution of nerves. The same author gives as other causes of herpes a disturbance of the parts incidental to pregnancy and menstruation in the female; uncleanliness, decomposing secretions. hot weather. obesity. forcible attempts at intercourse, impeded erection due to redundant prepuce, excessive venery, and masturbation; these various causes giving rise to excessive congestion of the genital organs, which the author believes to be the essential condition upon which herpes progenitalis depends. Imperfect or perverted sexual hygiene is peculiarly apt to give rise to more or less congestion of the genitalia with attendant disturbance of the delicate nerves supplied to these parts. That this condition of affairs may give rise to trophic changes in the mucous membrane and skin, as evidenced by the occurrence primarily of vesicles and secondarily of ulceration, is highly probable.[1]

There has been, so far as I am aware, no mention made by any of our numerous writers of the possible causal relation of syphilis to herpes progenitalis. I am convinced, however, from practical observation and experience, that many cases are directly dependent upon the syphilitic cachexia. I find quite a number of my syphilitic patients returning to me from time to time, with apparently typical crops of herpes upon the genitalia, which are obstinate to all local measures excepting the application of mercurials. Tonic and mild anti-syphilitic remedies are also required internally. I attribute the herpes in such cases to several causes:

First. (In some cases) local irritability incident to a pronounced chancre or mixed sore which has initiated the patient in his venereal trouble.

[1] Read before the North Texas Medical Association, December 12, 1889, at Gainesville, Texas.

[2] Journal of Cutaneous and Venereal Diseases, August, 1883.

[3] An interesting case of herpes, apparently dependent upon menstruation, recently came under my observation, in which the eruption instead of being located upon the genitals appears between the fingers. It comes on a few days prior to menstruation, and lasts for a day or two after its cessation. During this time considerable neuralgic pain in the arm and hand is complained of.

[1] I have under observation the case of a lady in whom herpes progenitalis develops coincidently with pregnancy; indeed, she regards the herpes as pathognomonic of pregnancy.

Second. Disturbed innervation and consequent trophic changes, incidental to the effects of the syphilitic poison, excessive medication (especially with mercury) and mental worry, upon the sympathetic system.

In regard to the areas involved by herpes progenitalis, Unna states that it rarely affects the integument of the penis, scrotum, or thighs, being limited usually to the glans penis. He also states that the eruption almost invariably corresponds with the course "of the ramus dorsalis penis," a branch of the pudic nerve. As far as my own personal experience goes, I have not noted any regularity of distribution of the herpetic vesicles, and I have seen a number of cases of the disease which were limited to the skin of the organ. The pain of herpes progenitalis is usually insignificant; however, if urine be brought in contact with the small ulcerations left after the rupture of the vesicles, the part becomes exceedingly tender and much burning and smarting are complained of. The disease is apt to occur about the borders of the meatus urinarius and occasionally just within the lips. I have one patient in whom a row of some half dozen small herpetic vesicles develops upon the right side of the meatus from time to time, and another in whom there is an occasional development of herpetic spots just within the orifice of the urethra. In such cases there is considerable pain and smarting during urination, and the disease seems to develop coincidently with nervous depression.

The two diseases for which herpes may be mistaken are chancre and chancroid. There is, of course, no difficulty in the differential diagnosis of herpes from typical chancre and chancroid when these diseases are fully developed, but in the incipient stages of these affections a mistake is very apt to occur. Fortunately, however, a few days' study of the case will generally clear up the diagnosis. Chancroid often begins as a small herpetiform vesicle or perhaps a group of vesicles or ulcers. This is probably due to the fact that the chancroidal virus or perhaps some other irritating material to which the parts are exposed during intercourse, produces herpes by simple irritation; chancroid developing at the site of the herpetic lesions at a variable period of time thereafter. The same explanation is true of some cases of hard chancre. The "herpetiform chancre" described by French writers is probably explained in this way. Unna has noticed a form of sore which is probably the so-called herpetiform chancre. With reference to this point, he says:

"I know only two affections which, because of their form and rarity, may be mistaken for herpes progenitalis, but only during the first few days of their existence. Chancres in the male now and then occur on the inner surface of the prepuce, are benign in their appearance, and slowly involve the surrounding tissues, and these at first sight look like herpetic erosions. They are the chancres of Tyson's glands which develop as inconsiderable epithelial proliferations in small contiguous groups of sebaceous glands—usually a group of from four to six neighboring glands are attacked. The round follicular openings are eroded, abnormally patulous and acutely hyperæmic, so as to give the impression of an herpetic erosion. If a simple dusting powder is prescribed for this affection, the case drags on and the typical herpetic course being followed, slight periglandular induration becomes manifest, succeeded by glandular disintegration and confluent, rapidly spreading ulceration, all of which impress the physician that he is dealing with a soft chancre, the course of which was protracted by its unusual seat. These exceptional cases, from the favorable prognosis they may elicit, are apt to discredit the physician's ability."

In the cases in which true syphilis follows an apparently herpetiform lesion of the genitalia, there will probably always be found upon close inspection, if the case be carefully watched from day to day, a greater or less degree of chancrous induration.

One of the reasons for the confusion that exists in the minds of physicians regarding the relation of certain atypical genital lesions to constitutional syphilis, is that they do not watch their cases with sufficient care and are prone to give a pronounced opinion in regard to the prognosis of such lesions without due consideration of the many sources of error. If these cases were more carefully studied, it is highly probable that the ranks of the dualists would be sadly depleted and many of those cases of syphilis which have apparently followed simple, non-indurated lesions of a herpetic, ulcerative, or chancroidal character, would be found to have been preceded by induration of greater or less degree which developed after the simple sore had apparently healed, and at a time when the patient's attention was no longer directed to the local difficulty. Again, as will be seen when we come to the consideration of the diagnosis of syphilis, induration may appear and disappear within a short time and its presence escape attention, unless the case be watched with extreme care from day to day.

When herpetic ulcerations become inflamed they are apt to assume physical characters strongly resembling those of true chancroid. Indeed, I am of the opinion that under favorable circumstances herpetic and balanitic ulcerations, or, for that matter, ulcerations of any sort whatsoever, may become transformed into a mild type of chancroid. I make this statement with a full appreciation of the wide clinical differences which exist between typical herpes and typical chancroid. I will, at this point, interpose a word of caution: Never give a positive opinion upon the character of herpes progenitalis, or, indeed, upon any apparently non-specific lesion of the genitalia in cases in which there has been a suspicious exposure within a suffi-

ciently recent date, without stating plainly to the patient the possibility of there having been a syphilitic or chancroidal infection which will develop sooner or later, and which the physician has no means of detecting prior to the appearance of the specific sore.

The treatment of herpes progenitalis is, in the majority of instances, sufficiently simple, but in a certain proportion of cases the disease is very obstinate. Simple dusting powders or astringent washes are all that is required in the way of local measures, as a rule. The powder which I have found to be most efficient is the preparation of oleate of zinc prepared by Parke, Davis & Co. Other preparations I have found to be unreliable, as they tend to become lumpy, and, consequently, produce irritation. Calomel, oxide of zinc, subnitrate and subcarbonate of bismuth, and lycopodium, singly or in various combinations, are useful. A simple astringent wash of iodide of zinc, five or ten grains to the ounce, or alum, in a strength of twenty or thirty grains to the ounce, may be used as a lotion. It may be necessary to touch the herpetic spots with nitrate of silver. When the lesions are very painful, morphine or cocaine may be added to the dusting powder. The essential point in the treatment is to keep the parts clean and dry. In some instances circumcision is advisable. In quite a number of cases it will be found necessary to adopt constitutional as well as local measures: tonics, such as quinine, iron, and strychnine, and where there is much nervous irritability, bromide of potassium, are indicated. In some very chronic cases, arsenic will be found to produce excellent results.

In the solitary case of menstrual herpes which I have seen, the bromides, with very small doses of ergot for a week or ten days prior to the menstrual period, have proved of some benefit, although the patient is still troubled more or less. In some cases of genital herpes in the male the occasional passage of a sound will prove beneficial as tending to relieve nervous irritability and congestion, to allay sexual excitability and, in a general way, improve the tone of the genital organs. I have seen a few obstinate cases which were apparently cured by matrimony. A few cases will be found to be absolutely resistant to treatment, but may at any time recover spontaneously.

812 Opera House Block.

THE MANAGEMENT OF BLEPHARITIS.[1]

By H. GRADLE, M.D.,
of Chicago, Ill.

According to some of the popular text-books on diseases of the eye, the inflammation of the margin of the lids would seem to be a very easily remedied affection. Anyone, however, who has had extensive personal experience will readily grant that such is not the case, and that the disease is very often rebellious, at least under the routine treatment most commonly advised. As this routine treatment—viz., the use of some mercurial preparation in the form of a salve—has proven neither the quickest nor the most reliable in my hands, I wish to offer some therapeutic suggestions based on my own experience.

We can distinguish clinically two forms of blepharitis, viz., the *ulcerative*, and the *non-ulcerative* or *squamous* inflammation of the palpebral margin. The former may be closely compared to eczema as seen on the scalp, while the scaly form of blepharitis resembles that affection of the scalp known as dandruff or seborrhœa, also described by Michelson in Ziemssen's *Cyclopædia* as alopecia pityrodes. It is difficult to say from clinical evidence alone whether these two forms represent different stages of the same disease, or are separate and distinct processes. The latter seems to me to be the more probable view. One of the reasons pointing toward this view is the fact that the squamous form invariably affects both eyes, while ulcerative blepharitis may be limited to one side. It is true, on the other hand, that something like transitional forms are occasionally met with. Sometimes small ulcers occur in the squamous form; but occasionally, too, one may find an abrasion of the scalp under a thick scale of dandruff. After the ulcers of the ulcerative form have been healed, the edge of the lid may remain inflamed for a while, but in that case it scarcely presents the scaliness of the typical squamous blepharitis.

Fukula claims that anatomically *blepharitis ulcerosa* is a disease of the papillary layer of the skin, while the squamous form of disease is located in the glands.

We are no better informed as to the causes of blepharitis than as to the etiology of the corresponding diseases of the skin in other parts. In the fresh pustules of the ulcerative form, Widmark has found the pus staphylococci. These undoubtedly cause the suppuration, but whether this is a complication or the cause of the disease is as yet undecided.

We do know, however, of certain predisposing influences which must be borne in mind in the successful treatment of this disease. Two of these conditions are commonly known to oculists, while the third has as yet received less general attention. The first of these is insufficiency of the lachrymal passages. Stricture of the duct or mere inflammatory stenosis, and especially inflammation of the tear-sac, may be the condition which favors the occurrence of the disease as well as the obstacle to the cure of blepharitis, particularly the ulcerative form. It

[1] Read before the Chicago Medical Society, January 20, 1890.

has further been pointed out by various oculists that eye-strain due to hypermetropia or astigmatism often favors the persistence of blepharitis, and may require correction by glasses before the inflammation of the lid can be removed by local treatment. A third condition which my experience has often taught me to recognize as a factor in the production of blepharitis is nasal disease. The mere coexistence of nasal anomalies and blepharitis would not prove the causal relation of the former, in view of the great frequency of morbid processes in the nose. I have, however, seen, a number of times, that nasal treatment alone improved and gradually cured a blepharitis which by itself had annoyed the patient so little that he had not sought my advice for the affection of the lids, but only for the nasal difficulty. On the other hand, I have occasionally met with cases of blepharitis, more especially the ulcerative form, in which I could not succeed in curing the patient permanently until I had turned my attention to the nasal cavity. I do maintain, however, that even in those cases where the nasal affection is presumably the influence which favors the occurrence of the disease and tends to perpetuate it, blepharitis can often, though not always, be cured by local means without removing the nasal anomaly. Hence I consider nasal anomalies not the exciting cause of blepharitis, but merely a predisposing condition. In view of the very many coincidences of blepharitis and nasal disease which I have seen, I believe this predisposing influence to be a frequent one. Predisposing nasal disease may be any form of nasal disturbance or anomaly as well as blockage of the post-nasal space by adenoid vegetations. The mode in which nasal anomalies influence the lids is probably by creating disturbances in the venous circulation. In some instances besides, nasal disease leads to lachrymation and insufficiency of the lachrymal passages.

Fuchs[1] has called attention to another cause, or rather predisposing condition in occasional instances of blepharitis, viz.. insufficient length of the skin of the upper lid, causing a slight gaping of the lid-aperture during sleep.

In the treatment of the ulcerative form of blepharitis, I can only endorse the majority of authors as to the use of the nitrate of silver stick. Its thorough application to the ulcers after removing the adherent crusts will stop the process sometimes at once, at other times after a few repetitions. The non-ulcerative inflammations which may still persist can then be made to yield by the use of an oxide of zinc salve. The latter has seemed to me to be more efficacious with the addition to it of about 5 per cent. of ichthyol. In other instances, I have succeeded well with pyrogallic acid, one part to eight of vaseline. I have seen either of these remedies succeed where mercurial ointments failed. It is well to remove with forceps all loose cilia in addition to this treatment.

The squamous form of blepharitis does not always yield to mercurial ointments, be it the white or the yellow precipitate, or the nitrate of mercury. It is necessary to remove in any case the scales which sometimes form very quickly. I have found that a 5 per cent. solution of chloral carefully applied with the finger to the edge of the lid facilitates the removal of the scales and may by itself cure the disease. A quicker treatment is the application of a pyrogallic acid ointment, which it is well to tell the patient may stain the skin temporarily.

Much quicker and more satisfactory results, however, I have been able to obtain by a treatment suggested to me by my dermatological friend, Dr. Zeissler, on the ground of the analogy between squamous blepharitis and seborrhœa of the scalp. This consists in the use of sulphur ointment, which I have never seen mentioned in ophthalmic literature. I have usually employed a 3 per cent. mixture of milk of sulphur with vaseline with the addition of 3 per cent. of resorcin. The latter seems to facilitate the removal of the scales, but I am not sure that its addition is essential. The application of this salve to the edge of the lid at night shows an influence which may be almost termed specific, only, however, in the squamous, not in the ulcerative form of the disease. Lids which have been red and unsightly for months and years often assume a normal appearance within one week. While it may be well to use the salve for some four to six weeks to guard against relapses, I have found that if its full benefit is not obtained in two or three weeks, it is due to some of the predisposing influences which then require attention. Of course, we should not attempt to cure a blepharitis without previously restoring the permeability of diseased lachrymal passages except on the patient's distinct refusal to submit to any operation. Where lachrymation persists it is scarcely possible to remove the blepharitis. In the case of hypermetropia or astigmatism the necessity for correction by glasses exists only if the eye-strain is either noticeable to the patient in any way, or if a few weeks of local treatment has not succeeded in curing the blepharitis. Finally, as to nasal influence, our therapeutic measures must also be guided by the circumstances. If the patient does not wish any nasal treatment, we may as well attempt to cure the blepharitis by local means, which will generally be successful. If this cannot be accomplished, there still is time to treat whatever disease of the nasal cavity may be found.

CLINICAL MEMORANDA.

MEDICAL.

Two Cases of Tetanus in Infants, with Remarks.—The two cases here detailed are both instances of tetanus in the newborn infant, but the first was evidently due to an injury to the head, and, therefore, can scarcely be classed as a case of infantile lockjaw, notwithstanding that the state of tetanic convulsion was present. The second is a typical case of trismus nascentium, about which so much has been written.

Case I.—I was called about noon of October 16, 1889, to see Lizzie M., single, white. The history given me was that, save some restlessness at night, she had been perfectly well until 1 A.M., of the morning I saw her, when she suddenly became totally blind. In the course of my examination, I found she was pregnant. A small quantity of urine was obtained, which was afterward found to contain casts and albumin. After I left the house to examine the urine, the woman had a terrible attack of convulsions, for which I gave her hypodermics of pilocarpine and nitro-glycerin and large doses of bromide and chloral. She soon had a second and last convulsion. Labor commenced almost immediately, and was terminated successfully by a high forceps operation under chloroform. The bones of the child's head were unusually movable, and I was able to depress the occiput to a great degree during my examination. The child was asphyxiated, but speedily revived and cried feebly. Its head was marked slightly over the right parietal protuberance and the temporal region on the same side. Two hours after birth it had a convulsion. I found it in the morning in the following condition: The left side of the face paralyzed; the right side of face the seat of *tonic* contraction, being much puckered and the jaw tightly shut. The right eye firmly closed, the left open. The left arm and leg were *not* paralyzed; both arms were drawn tightly to the side, the forearms flexed on the arms, and the fingers tightly flexed with the thumbs across the palms. The body of the child could be moved as if composed of a single piece, if lifted by the strongly flexed arms. The legs were rigid, the knees being slightly bent. Any disturbance of the child would bring on frightful paroxysms, in which it would almost succumb. It expired forty-eight hours after birth.

No post-mortem was allowed.

From the fact that severe compression and traction were made during delivery, and the additional fact that the left side of the face was paralyzed, it is safe to attribute the tetanic convulsions from which the child died to the use of the forceps. Though the convulsions were tetanic and not clonic, the case will scarcely come under the head of trismus nascentium, as it lacked many of the characteristics of that disease and had the potent cause of injury to the head by the forceps.

Case II.[1]—Mrs. G., colored, was taken in labor 6 A.M. on October 25, 1889. The os was but slightly dilated when first seen about noon, and I left with instructions to send for me when needed. About 6 P.M. I was hastily called and found the child, an unusually well-formed and large male, born. All went well until the morning of the ninth day, when the mother said that the child had worried all night and seemed unable to nurse. On examination I found all of the muscles of the face strongly contracted, the jaws firmly locked, the arms tightly drawn to the side with thumbs in the palms. It could swallow with but little difficulty, but was evidently in great pain. The umbilicus had not healed, a large ulcer covered with pus occupying the seat of the separated cord. The next morning the jaws were still firmly locked, and the least disturbance would bring on frightful tetanic convulsions. The child's face was constantly wrinkled by the contracted muscles. The head was retracted, the elbows bent, the thumbs in palms, the knees drawn slightly apart, legs bent at knees, the great toes adducted, and the other toes flexed. The child could be lifted without bending the spine, by placing a hand beneath the heels and occiput. The pupils were contracted. There was no strabismus. The child lived in this condition for twenty-four hours; the least disturbance causing the frightful paroxysms, but continuously in a state of tetanic convulsion. Temperature 105.5°.

Post-mortem, fifteen hours after death: The rigor mortis, which was marked two hours after death, had partially disappeared. Examination of the brain was not permitted. The condition of the bones of the head which existed during life persisted. The sagittal suture was widely open. The occipital bone was markedly depressed, being overlaid by the edges of the parietal. The umbilical ulcer was covered with a thin, dry crust. The lungs were highly congested, and the heart was distended with blood; otherwise the thoracic and abdominal organs were in a normal condition. The umbilical vein was patulous and was *not* the seat of any inflammation. The left hypogastric artery was filled with a clot, the right was free. I removed the bodies of the fifth and sixth thoracic vertebræ. The posterior part of the canal was the seat of extravasated clotted blood. There were no clots *within* the dura mater, though the veins were slightly congested.

There can be no doubt that this case is a true one of trismus nascentium, with the irritated umbilicus as the probable cause. Various and diverse theories have been advanced to explain this most curious and fatal disease.

In 1846, Dr. Marion Sims published a paper in the *American Journal of the Medical Sciences* in which he attributed the malady to a depression of the occipital bone, and claimed that the disease could usually be cured in its incipiency by simply turning the child on its side. He held that laying the child on its back, with its occiput resting on some hard substance, increased the depression of the occiput which always exists after birth. This theory was upheld by Dr. Hartigan, as late as 1884.

Dr. Watson, of Charleston, answered this article of Sims in 1851, and gave as the cause, inflammation in or around the umbilicus. In answer to the criticism that the umbilicus is frequently healthy in cases of trismus, he cites the fact that the wound which is the cause of traumatic tetanus is frequently found in a healthy condition at the onset of the disease.

Beside these two causes there is scarcely an accident to which an infant is liable that has not been cited as the causation of trismus. All authors agree that the disease is most frequent among the poor with bad hygienic surroundings, and that it may also occur in epidemics.

The latest theory I have seen is that advanced by A. D'Erpine and C. Picot, of Paris, in a volume on diseases

[1] Reported to Philadelphia Pathological Society.

of children published this year. They consider trismus nascentium, in common with ordinary traumatic tetanus, an infectious disease due to a specific microbe.

The treatment is highly unsatisfactory. Most drugs have been used without effect, the antispasmodics, notably chloral, being used most frequently at the present day. Sims's treatment by position alone is not mentioned by the later authors. Soothing and antiseptic dressings to the umbilicus, when it is irritated, seem of value. Prophylactic measures, viz., improvement in the hygienic surroundings, cleanliness of the infants, care in dressing the cord, seem to have been the important measures in breaking up the various epidemics.

M. H. Fussell, M.D.,
Physician to the Out-patient Department of the Hospital of the University of Pennsylvania
189 Green Lane, Manayunk

A Contribution to the Physiological Study of Infantile Digestion; a Preliminary Note.—For several months I have been engaged in the examination of the contents of the stomach, and also of the excreta, in nursing and artificially fed infants, and I desire to record in this preliminary note certain conclusions reached from these investigations.

The method has consisted in the chemical estimation of the amount of albumin, sugar, water, solids, fat, and ash in the stools of healthy and dyspeptic infants, and the examination of the contents of the stomach at varying intervals after feeding, by the chemical tests recently introduced for the study of gastric disease. These reagents have been Uffelmann's iron and carbolic acid test for lactic acid; Congo paper; the yellow tropœolin, and methyl-violet. Finally, the milk clot from the stomach has been microscopically examined to ascertain the degree of disintegration of the fat globules of the ingested milk, and to determine the presence of bacteria.

From these investigations the conclusions are reached that the stomach of the nursing infant and of the infant fed on sterilized milk, when both are healthy, contains neither hydrochloric nor lactic acid; when gastric catarrh is present or when high temperature has recently existed an acid, or acids, is found which reddens litmus, but does not respond to tests for hydrochloric and lactic acids. The milk clot from healthy infants, whether breast- or sterilized milk-fed, contains no bacteria, and its fat globules are reduced to granular matter in from half an hour to one hour after feeding. In proportion as gastro-intestinal catarrh exists the excreta of nursing and artificially fed infants contain an excess of undigested fat.

These results of investigation, combined with the clinical study of infantile digestion and its disorders, warrant the inference that in the digestion of the infant hydrochloric and lactic acids do not normally exist; that milk is clotted by a rennet ferment active in alkaline or neutral media; that the stomach serves the purpose of a coagulating bottle which is empty in less than an hour after feeding; that digestion and absorption proceed according to the activity of the pancreatic and intestinal secretions, the pancreas being especially concerned in normal digestion and the lack of its functional activity being most apparent in gastro-intestinal disease. It is my purpose soon to discuss further and elucidate these points.

Edward P. Davis, M.D.,
Professor of Obstetrics and Diseases of Children in the Philadelphia Polyclinic; Obstetrician to the Philadelphia Hospital

ANATOMICAL.

A Diverticulum from the Ileum.—In recording the following case I desire chiefly to call attention to the curious and interesting blind pouch which was discovered attached to the ileum, but also to note a peculiar inflammation of the sigmoid flexure of the colon. Further, I trust that this imperfect clinical record may aid in the appreciation of the peculiar difficulties in diagnosis constantly encountered by medical officers in hospitals for the insane:

Barbara R., a German, aged sixty-four years, married; transferred to this hospital from the Insane Department of the Philadelphia Hospital, where she had been for eleven years, after the fire which destroyed nearly all the buildings of that department in 1885.

Her mental condition during the four years of her residence here was that of chronic mania with delusions, and I have no doubt she was in the same condition while at the Philadelphia Hospital. Like many cases of this kind, she did much useful work, going out to the laundry and ironing-room regularly during the greater part of the time she was here. She was almost constantly either muttering to herself or talking aloud to persons whose voices she imagined she heard. She also had hallucinations of sight, and, in consequence, many delusions, and gave irrelevant answers to questions, or no answer at all.

About the middle of last August she began to lose much of her energy for work, but continued scolding and muttering to herself, as was her custom.

October 20th she vomited several times, and had some diarrhœa, the stools being light in color; she was put to bed, and the next day there was vomiting, but no diarrhœa. The general asthenic condition of the patient appeared to be out of all proportion to the objective symptoms, which did not seem to be grave. Strangulated hernia was suspected, but careful examination failed to discover its presence. She had cold sweats and subnormal temperature, and died October 24th.

Autopsy, eighteen hours after death: Body much emaciated; rigor mortis not marked. Heart firmly contracted; posterior leaflet of mitral valve strongly adherent in the half of its area nearest the line of insertion, so that the free surface of the valve was only about one-half of its normal area. Lungs normal. Small intestine normal in calibre, except in three or four places, where the lumen was contracted from one-half to three-quarters. The smallest length of intestine with diminished calibre was about four inches, the longest a foot.

Proceeding from the ileum, about two feet above the ileo-cæcal valve, an appendage or diverticulum was discovered. It was about four inches in length, and with a lumen of sufficient size to permit the introduction of the middle finger. It joined the intestine nearly at right angles, and was of a uniform diameter in its entire length, though a trifle smaller nearer the extremity than at the junction with the bowel, as seen in the cut. A slight uniform dilatation of the ileum was noted in the region of the bowel from where proceeded this process. The diverticulum, or "blind gut," ended in a rounded, slightly sacculated extremity, and was filled with soft fæcal matter.

The large intestine varied greatly in its lumen; in the

ascending and part of the transverse colon being very large, then a sudden diminution in the diameter, until it would not permit the introduction of an object larger than the thumb. This contracted portion of the bowel was about ten inches long. It terminated suddenly in

an expansion, which, in its maximum lumen, was about twice as great as that of the normal bowel. Lower down in the colon—about the sigmoid flexure—for the extent of nearly a foot, the bowel presented a livid, marroon color, and at some points was almost black. A thick, tenacious material was strongly adherent to the interior aspect of the inflamed portion of the gut. No signs of inflammation in other parts of the bowels were noticed.

Remarks.—This peculiar inflammation, amounting almost to gangrene, in the lower part of the colon, possibly was caused by an embolus or thrombus, which cut off the nutrition of this part of the bowel—at all events, this local trouble was probably the immediate cause of death, although in a patient of this kind grave organic disease might have coexisted and have escaped notice—even at the post-mortem.

That anything more than an approximate diagnosis was possible I cannot believe. Indeed, such conditions in a rational person would certainly have been difficult, and perhaps impossible, to diagnose. As to the diverticulum, it might have been congenital or acquired. The fact that the bowel was so enormously contracted and dilated (a condition I have a number of times noted in autopsies upon the insane, and which I believe to be due to the habit of constipation) is favorable to the latter view. On the other hand, the peculiar form and size of the diverticulum would seem to indicate that the anomaly was congenital.

For the accompanying drawing I am indebted to the kindness of Dr. G. R. Trowbridge, of this hospital.

Theodore Diller, M.D.,
State Hospital for the Insane, Danville, Pa.

THERAPEUTICAL.

Compressed Pills of Salol and Terpine Hydrate in "Colds."—For two years past I have been using, in my service at the Philadelphia Polyclinic and in private practice, in the treatment of "coughs and colds"—that is to say, mild attacks of bronchitis and of catarrhal fever, acute and subacute, a pill consisting of

Salol } . of each 3 grains;
Terpine hydrate }

made and compressed for me by Mr. Kyner, the apothecary of the Polyclinic. These pills are now kept in stock for dispensing, or for sale to apothecaries by Messrs. Kyner & Kyner, and by Mr. Frank E. Morgan. The dose is one or two pills every second, third, or fourth hour, according to indications.

The results of this plan of treatment are quite satisfactory, especially in those cases of "general cold" or mild catarrhal fever, in which there exists more or less muscular and articular pain, associated with symptoms of bronchial catarrh; cases which I formerly treated with cinchonidine salicylate. In the more severe type of "colds," approaching more closely the typical influenza, of which we always see a number of cases in this city at this season of the year, as well as in the early Fall and in the early Spring—it is well to combine with the treatment mentioned, the use of some good alcoholic preparation of bark, or even quinine and whiskey. Fluid extract of coca is also quite useful. When the nasal symptoms are troublesome, they may be completely relieved by the judicious use of belladonna or atropine. The dose will vary with different individuals. It should be just short of the quantity required to produce full physiological effect. In cases where severe lumbar pains suggest renal congestion, the prompt administration of some simple alkaline diuretic, such as solution of ammonium acetate, with spirits of nitrous ether, is of benefit.

Solomon Solis-Cohen, M.D.

MEDICAL PROGRESS.

The Preparation of Lister's Double Cyanide Gauze.—Sir Joseph Lister, in the *Lancet* of January 4, 1890, describes the method of preparing his new surgical dressing thus: Cyanide of potassium, cyanide of mercury, and sulphate of zinc are mixed together in solution in quantities proportioned to their atomic weights; the cyanide of potassium and cyanide of mercury being dissolved together in 1½ ounces of water for every 100 grains of potassium cyanide, and added to the sulphate of zinc dissolved in three times that amount of water. The precipitate is collected on a strainer, and when well drained is washed with two successive portions of water, equal in quantity to that used for the solution—viz.: 6 ounces for every 100 grains of potassium cyanide; at least this amount of washing being essential in order to free the precipitate sufficiently from the highly irritating soluble salts which are associated with it in its formation. The precipitate having been thus washed and drained, but not dried, it is thoroughly diffused with pestle and mortar in distilled water (6 ounces for every 100 grains of potassium cyanide), containing in solution 1 part of hæmatoxylin for every 100 parts of the cyanide salt, the amount of which is known from the circumstance that the dry product of cyanide salt is almost exactly equal in weight to the potassium cyanide employed. Hæmatoxylin is readily

soluble in a small quantity of hot water, and remains in solution when added to a large quantity of cold water. The cyanide salt, while it precipitates the hæmatoxylin, changes its color to a pale-bluish tint. This is advantageously enhanced by the addition of a little ammonia to the mixture in the proportion of 1 atom of ammonia to each atom of hæmatoxylin. More than this proves prejudicial. The ammonia is added in a dilute form, and it is convenient to have the dilution such that one fluid drachm of the ammoniacal liquid shall correspond to one grain of hæmatoxylin. The dye is further economized by allowing the ammoniated mixture to stand for three or four hours, and stirring it occasionally, so that the ingredients may react thoroughly upon each other. If the mixture is filtered immediately, there is considerable loss of coloring matter. The dyed salt having been drained and dried at a moderate heat, is levigated, and may then be kept for any length of time. When employed for charging a dressing, it is diffused by means of pestle and mortar in solution of bichloride of mercury (1 to 4000) in sufficient abundance to drench the fabric thoroughly, for which 4 imperial pints to 100 grains of the salt will be found adequate. This will give a percentage of between 2 and 3 of the cyanide to the dry gauze. The gauze should always be used moist; and if it be prepared for immediate use, the process of drying may be omitted, the gauze, after being hung up for a while to drain, being further deprived of superfluous moisture by placing it in a folded sheet. It may afterward be conveniently kept moist by wrapping it in a piece of mackintosh cloth. When obtained dry from the manufacturer, it should be moistened again with the weak corrosive sublimate before it is used.

The Diagnosis of Syphilis and Malignant Disease.—DR. EDUARDO CONTE (*Il Progresso Medico*, December 1, 1889) gives some striking illustrations of the difficulties which often surround the diagnosis of syphilitic formations from cancerous and other malignant neoplasms. Though the subject is well worn, it is one of perennial interest to surgeons, as every one who has ever followed the practice of a hospital even for a few months must have seen cases in which swelling or ulceration due to syphilis has been mistaken for cancer, with the result, possibly, that some organ (generally the tongue) has been removed or mutilated without necessity. The opposite mistake is, perhaps, still more common, and under the plea of "giving the patient a chance," malignant disease is allowed to run on whilst precious time is lost in futile antivenereal medication. Under these circumstances, as Mr. Butlin well puts it, the "chance" is given, not to the patient, but to the disease. Dr. Conte's first case was one of syphilitic disease of the lower lip in a married lady, aged thirty-four, with two healthy children. She noticed a pimple on her lip, which, after some time, broke, the ulcer discharging a thin purulent secretion and showing a marked tendency to spread. It was repeatedly cauterized without effect, and the submaxillary glands became much enlarged. In the absence of any history or evidence of syphilis, the case was diagnosed as one of epithelioma, and the patient was urged to have the tumor excised. Dr. Conte, however, considering that the tumor was softer in the middle than elsewhere, and taking into account the brownish-red color of the ulcer, the thin purulent discharge, the absence of hæmorrhage, together with the painlessness of the swollen glands, came to the conclusion that it was syphilitic, and treated it with iodoform, which effected a cure. Subsequently condylomata appeared about the anus and vulva, with a syphilitic rash upon the body and enlarged glands in the neck and groin. The infection was traced to smoking cigarettes which a young man with mucous patches used to light for the patient. In another case an officer of the Italian navy, aged forty-five, had an ulcer on the scrotum which was diagnosed as malignant. The ulcer was circular in form, measured one centimetre in diameter, and had raised edges. There was a thin discharge, and the surrounding tissues were thickened; not far from the ulcer there was another about half as large. The inguinal glands were enlarged. No history of venereal disease beyond gonorrhœa in early youth could be obtained. Dr. Conte, nevertheless, diagnosed the case as one of subcutaneous gummatous nodules. Iodide of sodium was given internally: cotton-wool soaked in a 1 : 1000 solution of corrosive sublimate was applied to the ulcers, and the same preparation was injected hypodermically to the amount of 1 centigramme a day, the patient, who would not listen to any hint that the disease was syphilitic, being led to suppose that it was morphine that was injected for the relief of nocturnal headache, of which he complained. Complete cure followed this treatment. Several other cases illustrating the difficulties in the differential diagnosis of these affections are also reported by the author. —*London Medical Recorder*, December 20, 1889.

Flushing the Peritoneum after Abdominal Section.—With a novel object in view, MR. JOHN D. MALCOLM (*Lancet*, January 11, 1890) insists upon the importance of washing out and distending the peritoneum with water after laparotomy. If, as he says, in finishing the process of washing out the peritoneum, the abdominal cavity be distended with fluid, the intestines must be floated up toward the highest level of the cavity. As the intestines are thus buoyed up by the fluid, it is obvious that changes in the relative positions of the various coils must be greatly facilitated, while the traction which is at the same time brought to bear on the mesentery, must tend to straighten out that membrane in its attachments to the posterior abdominal wall and to the bowel, and so to undo any acute twists which may exist. The mesentery and bowel will thus be thrown into natural folds. If the fluid be then simply permitted to flow out of the abdominal cavity, or be carefully sucked out of the pelvis by means of a tube, without sponging or other mechanical disturbance, the intestines will tend to settle down in a natural position, just as they do when an ascites is relieved by tapping. In no other way can so satisfactory an adjustment be assured. It seems, therefore, that one of the most important, if not the most important, of the advantages to be secured by the free use of fluid in cleansing the peritoneal cavity, is the facility which this method of procedure affords for securing a natural disposition of the coils of the gut. A normal position being thus obtained, adhesions may form without giving rise to serious consequences.

Of interest in connection with the consideration of the normal arrangement of the intestines of these cases, is the assertion that patients who suffer much from chloroform vomiting after an abdominal section, not infrequently recover more satisfactorily and more quickly than those

who are not so affected. Dr. Malcolm suggests as an explanation, that if a patient be constantly straining and retching for five or six hours or more after an operation, however much the intestines may have been displaced, the shaking of the abdomen must tend to bring them into a natural position again before adhesions can take place or become firm. If, on the other hand, there be little or no vomiting, and if the patient lie quiet, adhesions may form so as to fix the more or less paralyzed intestines in the position in which they have been placed, and so left, by the hand of the surgeon, which may not be a natural one.

The Doses of Digitalis and Strychnine.—In the *Therapeutic Gazette*, January, 1890, Dr. Henry M. Field expresses very decided views upon the doses of digitalis and strychnine usually employed. Long experience has convinced him that for cardiac conditions demanding digitalis, whether neurotic or structural, five drops of the tincture three times daily is usually a sufficiently large quantity. Press the remedy further, and evidence will be presented of a tetanized heart, although perhaps in slight degree. Here it is to be remarked that the chief experience of this writer has been in cases of weak and irritable hearts, caused, it may be, by various excesses, and most often encountered in adults who have long been overburdened by business responsibilities. Few other results in practical therapeutics are so sure to be satisfactory as are those which follow the use of digitalis in such conditions; but success depends upon reform, so far as possible, in the fault which produced the cardiac difficulty, and upon systematic regular ingestion of the tincture in doses of not more than five drops three times daily for months.

The alkaloid strychnine he considers should never be prescribed, for the reason that it is extremely insoluble, and when the drug is required it should be administered as a soluble salt, such as the sulphate. When the sulphate of strychnine is prescribed as an adjuvant to a laxative, the dose should be not less than one-fortieth of a grain. A pill composed as follows is used by Dr. Field as an aperient:

R.—Aloin	⅓	grain.
Sulphate of strychnine . .	$\frac{1}{40}$	"
Extract of belladonna . . .	$\frac{1}{10}$	"
Powdered ipecacuanha . .	½	" —M.

One such pill will usually be found sufficient.

The Hypodermic Syringe in Diagnosis.—Aspiration by means of the hypodermic syringe has come to be so much employed of late years, that a simple suggestion of a means by which the result may be rendered more reliable seems worth noting. One of the strongest objections to the ordinary use of a hypodermic needle for diagnostic purposes is that a positive result can alone be regarded as of certain value. The fact of not obtaining pus or other fluid, even when several punctures have been made, affords no reliable evidence as to the non-existence of a fluid-containing cavity. In the majority of cases pus will readily flow through a needle, but the lack of reasonable certainty in the event of a negative result is highly unsatisfactory. A suggestion offered by Dr. F. T. King is as follows: Draw boiled water into the syringe until it is about one-third full, and, after puncturing, slowly expel a few minims into the supposed cavity, then gently withdraw the piston, and if a collection of fluid exist, we are practically sure to obtain a specimen of it for naked eye or microscopic identification. He first tried this plan in a case where only a negative result could be obtained by the ordinary method, though the pus flowed freely when it was diluted. Since then he has used it in a large number of cases with the view of testing its value, and has never failed to satisfy himself with a single puncture. There is rarely any necessity to expel more than about three minims of water, but, if this fails, the piston may be driven further home, or even worked in and out several times.

Dr. King thus summarizes the advantages of his method: 1. The needle is cleared. 2. The tension of the fluid is increased. 3. The fluid is rendered thinner.

When a syringe is used in this manner, great care is necessary in thoroughly cleaning and disinfecting the barrel after each injection.—*British Medical Journal*, January 11, 1890.

Codeine in Ovarian Pain.—Dr. Freund, of Strassburg, has recently used codeine in a large number of cases of abdominal pain from various causes, with the view of testing the assertions of Dr. Brunton that the drug is of especial use in intestinal or pelvic pain. His results seem to indicate that Brunton's views are somewhat exaggerated.

Pain from acute uterine affections, such as dysmenorrhœa, Freund found, was not as quickly relieved with codeine as with morphine, and the relief was of shorter duration. In pain from pelvic exudates and tubal disease the drug was also of but little value. In ovarian pain, however, whether from prolapse, oöphoritis, perioöphoritis, or neuralgia, the relief afforded by codeine was prompt, unmistakable, and more or less permanent even when small doses were given. The amount usually administered was about half a grain three times daily in pill form, and in but few cases was it necessary to increase this quantity. His experience coincides with Brunton's that no disagreeable or harmful effects follow the use of the drug. It does not stupefy, diminish the appetite, nor constipate. He prescribes the pill for one month after an attack of ovarian pain, and warmly recommends the drug for the above conditions.—*Therapeutische Monatshefte*, November, 1889.

Three Diagnostic Signs of Melancholia.—In the simple form of melancholia, as is well known, there is melancholy, which is usually unattended by delusions, hallucinations, or illusions, although there may occasionally be delusional or hallucinatory tendencies, but there is none of the agitation or stupor of the other forms. The simple forms of melancholia are often extremely difficult to diagnose, especially in the early stage, as the reasoning powers, the memory, and the perceptions are then often seemingly unimpaired, or not more affected than is possible from many unimportant causes. Patients suffering from this mental disease frequently figure as neurasthenics, and are confidently treated as such until some determined and frightful suicidal or homicido-suicidal attempt throws startling light upon the true nature of the malady. These, too, are the cases of mysterious suicides which are accounted for on some theory of

rejected love or high-flown sentimentalism. Any certain diagnostic symptoms in this class of cases should be for these reasons of value. In sixteen cases of melancholia which have come under the observation of DR. LANDON CARTER GRAY in the last eighteen months, he has found three constant symptoms, viz., melancholy, marked insomnia, and a post-cervical ache. The post-cervical ache is an aching pain in the back of the neck and head, and sometimes extending to the shoulders. It is usually described as a distress or ache, although it may occasionally be neuralgic in its character, and not infrequently passes into neuralgic paroxysms which will last for a day or two.

The insomnia is usually one of the earliest symptoms of the disease, but has no especial characteristics.—*Journal of Nervous and Mental Diseases*, January, 1890.

The Surgical Treatment of Tubercular Peritonitis.—In the *Centralblatt für Chirurgie*, No. 40, 1889, SPAETH holds that the statistical results of the operative treatment of peritoneal tuberculosis must be received with considerable reserve, owing to the absence of identification of tubercle bacilli. Of four cases in Prochownick's clinic, in which the tubercular nature was thus proved, one died early from collapse, and the other three within a few months from general tuberculosis. Although he does not on this account deny the possibility of cure, Spaeth believes that the statistical results are doubtful. He submits the following propositions:

1. In primary abdominal tuberculosis, without implication of other organs, laparotomy is satisfactory.

2. In peritoneal tuberculosis, with involvement of the female generative organs, the operation has as yet given no definite results, whether these organs have or have not been removed.

3. If the intestines be involved the operation is only palliative.

4. In genital tuberculosis, without peritoneal invasion, operation should be performed as early as possible, but an early bacterial diagnosis is difficult to obtain.

5. Primary peritoneal tuberculosis is much rarer than is generally supposed, hence the diagnosis should be made with care, and only accepted if confirmed by bacteriological observation.—*Medical Chronicle*, January, 1890.

The Extirpation of Benign Tumors of the Thyroid.—The excellent results obtained by MR. CHARTERS SYMONDS in his treatment of these growths by extirpation, as detailed by him at a recent meeting of the Clinical Society of London, will serve to draw the attention of other surgeons to the method of treatment therein recommended. Mr. Symonds laid stress upon the following points: The median incision is to be made in all cases and the capsule of the cyst to be looked for—as a rule, it is at once seen if the tumor be superficial, or a part of it projects beyond the margin of the gland; when the cyst is found to contain fluid, all is to be evacuated and the cyst peeled out, or, if the tumor be solid, it is to be enucleated. In some cases the margin of the gland must be raised up. In two of Mr. Symonds's cases the lobe was removed on the supposition that the growth was incapsuled intimately; but afterward this was not found to be the case. All his eight cases did well, primary union resulting in every one of them; and there was no hæmorrhage in the simple cases. The rapid recovery of his patients generally contrasts favorably with the much slower progress of patients treated by other methods. Thus, tapping and injecting with perchloride of iron is apt to produce hectic, and some patients thus treated have almost lost their lives. In fact, when much solid material exists in the growth injection is unsuitable. If such cases be treated by injection, serious results are likely to occur. If the cyst be opened and sutured to the skin, and stuffed, the case is long under treatment, the resultant scar is large, and there is more danger than when excision is performed. Possibly a small incision and scooping out of the tissue may in some cases succeed; but it appears to be attended with much danger of hæmorrhage. In one of Mr. Symonds's cases which was exhibited, the cicatrix was only an inch and a quarter long, although an adenocystoma, measuring three by two inches, had been removed. In this case the fluid had been first evacuated, after the manner recommended.—*British Med. Journal*, January 11, 1890.

The Treatment of Chronic Prostatitis.—PROFESSOR HENRICH KÖBNER, of Berlin, has for some time used, with good results, the iodide and bromide of potassium, administered by the rectum, in the treatment of chronic prostatitis. At first the salts were administered with cocoa butter in the form of suppositories. These, however, frequently caused irritation and burning of the rectum, which was due to the fact that the suppositories were slow in melting. For this reason he now uses the drugs in solution as enemata. The formula which he recommends is as follows:

R.—Potassium iodide	4 grains.
Potassium bromide	3 to 4 "
Extract of belladonna	⅓ grain.
Water	5 drachms.

This amount is to be added to from 1½ to 3 ounces of warm water and injected once, later twice, daily. Further in the course of treatment the iodide and bromide may be increased to three times the above amounts.—*Therapeutische Monatshefte*, November, 1889.

Sulphur in the Treatment of Diphtheria.—Sublimed sulphur is strongly recommended as a local application in diphtheria, by DR. CHARLES SMITH, of Australia (*Australian Medical Journal*, December 15, 1889). The throat is first mopped with a solution of tannin in glycerin; simply painting with a brush is not sufficient, as the object is to remove the membrane as far as possible, and to leave a sticky surface. A small quantity of sulphur is then insufflated upon the diseased surface, and as it should remain there for at least fifteen minutes, the patient is neither allowed to expectorate or swallow for that length of time. The author considers it essential to repeat this at least every hour, day and night. The small amount of sulphur swallowed occasionally relaxes the bowels, but not to a great extent, unless larger amounts than necessery are used. According to Dr. Smith, with this treatment the diphtheritic process usually quickly ceases to spread and begins to improve within forty-eight hours, though appreciable change is not always so rapid. How this method of treatment is applied in cases of laryngeal diphtheria does not appear from the paper in question.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

THE TREATMENT OF SYMPTOMATIC HÆMORRHAGE.

PROBABLY no symptom is more alarming to the friends or, as a rule, a source of greater anxiety to the medical attendant than hæmorrhage. Its immediate checking naturally seems to the bystanders the first duty of the physician, yet in many cases it would be far better for the patient to lose some blood and so have the benefit of nature's method of relieving, by this safety-valve leakage, the diseased condition of some organ, than that the hæmorrhage should be controlled by medicinal or other treatment. Urged by the patient's friends, and feeling the "necessity of doing something," the physician mayhap often controls the hæmorrhage to the detriment of some diseased organ whose relief could be secured in no other way so speedily or completely as by the drain of blood from the overfilled vessels.

In hepatic disease attended by portal obstruction the rectal hæmorrhages, often too actively treated, may relieve symptoms which otherwise might be overcome with difficulty or not at all. By epistaxis nature often takes it upon herself to relieve intracranial congestion and, if read aright, will offer material assistance as an indication of the proper mode of treatment to be adopted. Many other examples of this safety-valve leakage from over-distended vessels might be adduced. In all cases to treat hæmorrhage as hæmorrhage, and not as a possible symptom of disease of deeper origin, is as irrational as to treat all headaches with nerve sedatives. In the *Gazette Hebdomadaire de Médecine et de Chirurgie* for November 8, 1889, is an excellent article by Guinard upon the treatment of hæmorrhage from other than large vessels. He relates several cases of epistaxis cured by the application of a vesicatory over the hepatic region. In some of the cases so treated the diagnosis of hepatic disease had already been made; in these the hæmorrhage was arrested by the measure employed; in others the cessation of hæmorrhage after the application to the area named led to the detection of previously unrecognized hepatic disease; in a third class the application failed to control the hæmorrhage, and in these no hepatic lesion was present. He also relates cases of hæmorrhage due to malarial infection and to disease of the kidneys, which ceased under treatment applied to the underlying cause.

Epistaxis is so frequent an occurrence in apparently perfectly healthy individuals, and of itself is so seldom of serious consequence that we may, unless we are constantly on our guard, pay attention to the surface play without considering its significance as the outward and visible sign of some causative visceral disease. As with coryza, so with epistaxis the symptom may be heroically attacked, leaving the underlying renal disease to pursue its course unnoticed.

The rational method of treatment is to remove the cause of symptoms produced, and only after careful investigation of other organs, that could be capable of producing the symptom, should the hæmorrhage be considered as idiopathic and due to some local condition.

Were we to picture fully to ourselves the physical condition of the diseased organs that we have to deal with, and, so to speak, to put ourselves in their place, we might often change materially our plan of attacking the symptoms presented.

Too often does the physician, urged (perhaps against his will) to stop the hæmorrhage, turn with confidence to ergot as the great hæmostatic, and in giving the remedy feel that he is "doing something" to the quieting of his own conscience and of the clamor of the patient's family. No matter from what source the hæmorrhage may come, or to what cause it may be due, ergot is looked upon by many as the panacea for hæmorrhage. From the fact that uterine hæmorrhage is controlled by ergot,

the conclusion is drawn that all hæmorrhage can be surely and safely checked by the same means; yet probably the action of ergot as a stimulant to the contractile power of the uterine tissue has more to do with its ability to stop post-partum or other hæmorrhage from the same organ, than has any hæmostatic property possessed by the drug.

That ergot is a powerful vaso-motor stimulant makes it of vast value in the treatment of such hæmorrhage as arises from disease of the vaso-motor system in which subcutaneous, submucous, or external hæmorrhages occur. Here its action is intended to affect the whole bloodvessel system of the body, and its use is rational. It is far different when we have to deal with hæmorrhage due to the rupture of a vessel from local disease of its walls or of the surrounding tissue. By giving ergot in the latter condition we increase blood-pressure enormously by contracting *all* of the arterioles of the body, we increase the strain upon the diseased and weakened vessel-wall as well as upon those of the healthy vessels, and we must of necessity not only render further rupture possible, but also increase the outflow from the bleeding vessel, thereby perhaps destroying the chance of clot-formation, by which alone the leak can be repaired. It is impossible to see how ergot could have any selective action upon the ruptured vessel, picking it out from the rest and diminishing its calibre, and it is but natural to believe that a vessel so diseased as to suffer rupture of its wall, cannot contract so well as do the healthy vessels throughout the rest of the body.

If the above view is correct, it is improper to administer ergot for the checking of hæmoptysis, and unwarrantable to attempt to prevent a recurrence by repeated doses of the drug after the first leak has been plugged by a clot. In cerebral apoplexy the same remarks would apply with even more force, as we have here to consider the fact that the more fully the cerebral vessels are dilated, the less room is there for the accommodation of the outpoured blood, and that by contracting the unruptured bloodvessels we not only increase the force of the blood stream through the already ruptured vessel, but also make room for more blood to be poured out, and invite its exit through the rent. It is not the blood *in* the cerebral vessels that causes the damage, it is the blood *outside* of them.

Were a leak to occur in a branch of the conduits leading from a reservoir of water, the method adopted to check the outflow would surely not be to narrow or occlude all other branches, or to remove all external opposition to the free discharge from such a leak; yet with local disease of one part of the vascular system the analogy will hold, as the atheromatous and friable cerebral vessels, and the thickened infiltrated vessels in the walls of a pulmonary cavity certainly cannot be capable of much contraction under the influence of ergot or any general vaso-constrictor.

Far better is it to quiet the strength of the blood current, to divert the stream so far as possible into healthy channels widened for the reception of as much blood as is possible, to quiet the heart's action and so allow nature unopposed to attempt to plug the leak by clot-formation.

With some modification the same method of reasoning applies to the use of ergot in the hæmoptysis of mitral disease, where by the administration of the drug all of the arterioles are contracted, and thereby more obstruction opposed to the blood flow from the already incompetent heart. Here the method of attacking the cause would be by aiding the heart to keep up the lesser circulation, while at the same time endeavoring to lessen, instead of increase, the *vis-a-fronte* in the greater circulation. A severe, but not fatal, hæmorrhage, if unchecked by medicinal measures, continues until syncope occurs with practical absence of blood-pressure. If the syncope or rather the low blood-pressure, last sufficiently long, clot-formation occurs at the bleeding point and the hæmorrhage ceases. If the patient be raised from the recumbent posture, hæmorrhage may recur from the rise of blood-pressure produced by the change of position sweeping out the clot that may have formed. The pointings of nature are always wise and safe, and the more we assist instead of opposing her and the more we attempt to imitate her methods, the more rational will be our treatment and the more certain our results.

THE UNITED STATES PHARMACOPŒIA OF 1890.

THE fact that the United States Pharmacopœia of 1890 is about to be acted upon by the decennial convention next spring, should excite very considerable attention among the members of the medical profession everywhere. It is of the gravest importance that the physicians of the United States should send as representatives to Washington a band of men who will be representative of all that is practical and nothing that is commercial. At the last

revision, the commercial element was so strong that science had little or no standing, simply because the physicians who should have been there failed to appear, either through lack of interest, fear of expense, or because the various medical bodies of the country had not sent delegates properly accredited. There is no doubt, however, that the physician should have a large amount to do with such a task, for it is his practical application of remedies that forces the pharmacist to keep on his shelves the drugs required. He alone can separate, by reason of his experience, the useless drugs from the good, and is best qualified to state what new ones shall be inserted in the list. Once more, it should be remembered that purely commercial or business principles animate the druggist, who is only an educated tradesman, carrying on his business solely with the idea of large pecuniary recompense. That such reward is sought after by the majority of physicians is of course true, and were it not for the well-known lack of business forethought of professional men, they would see that an immense amount of pecuniary loss may ensue if they are listless and careless in regard to this most important subject. To any one who has given it a half hour's thought, it must be evident that all leaves, rhizomes, roots, or flowers of a plant must of necessity vary greatly in the quantity of the medicinal substances which they contain, and it has been proved again and again that fluid extracts vary as much as twenty per cent. in the amount of their active principles. Even such a commonly used drug as aconite has been found to vary from one to twenty per cent. in a dozen stores in New York and Philadelphia. The reason of this is evident when we remember that nothing is required of the druggist by the Pharmacopœia as to the strength of the crude drugs employed, and that the temptation must always be to buy the cheapest raw materials rather than the more highly priced assayed leaves or roots. The physician has too often to submit to unjust criticism because his patients fail to be benefited by the treatment they receive, and everyone sees cases get well after using a certain drug given by one doctor, although it has failed in the hands of another, simply because in one case the preparation used was poor and in the other good. Aside from the mere pecuniary loss entailed, the questions of life and death, humanity and personal confidence are at stake.

The query as to the manner in which this crying evil is to be put down is difficult of solution. Fortunately we are possessed of the alkaloids of most of the remedies generally employed, and these should be resorted to in all cases where doubt can possibly exist. Be the means what they may, some clear, distinct plan of action should be reached when the wise-heads of the convention come together, which will do away with uncertain therapeusis and give the physician reliable tools with which to practise his calling.

REVIEWS.

The National Medical Dictionary; including English, French, German, Italian, and Latin Technical Terms used in Medicine and the Collateral Sciences, and a Series of Tables of Useful Data. By John S. Billings, M.D., LL.D., Edin. and Harv., D.C.L. Oxon., with the Collaboration of W. O. Atwater, M.D.; Frank Baker, M.D.; S. M. Burnett, M.D.; W. T. Councilman, M.D.; James M. Flint, M.D.; J. A. Kidder, M.D.; William Lee, M.D.; R. Lorini, M.D.; Washington Matthews, M.D.; C. S. Minot, M.D.; H. C. Yarrow, M.D. Two volumes. Philadelphia: Lea Brothers & Co., 1890.

Familiarity with the workings of the plan upon which these volumes have been constructed, attained after long-continued use of their contents, is the only trustworthy criterion upon which to base a thorough review. Inasmuch as sufficient time has not elapsed to permit the employment of such a test, two substitutes offer themselves—comparison with other works of similar character, and a necessarily limited search for words, phrases, and abbreviations as they are encountered in the medical literature of the day.

The labor of comparison quickly demonstrates that this work in accurate derivation, concise definition, and general adaptability, is the equal of all rivals and the superior of the majority. The search for terms current in medical literature reveals that the object of the Dictionary to supply those in use "in English, French, German, and Italian, including the Latin medical terminology of all these languages," has eventuated in a satisfactory consummation. Perhaps the most striking feature, in addition to the industry which has gathered practically every medical term in current use, is the rare skill in condensation which is displayed, so that each definition is concise, often necessarily brief, without, however, sacrificing clearness to this brevity. This commendable feature will appeal to every man who does not turn to a dictionary to find lengthy essays upon the words it contains, or go to an encyclopædia to hunt for mere definitions and synonyms. It would be comparatively easy to point out numerous characteristics which readily attract the busy student—the satisfactory method of cross references, the redefinition of synonyms of dissimilar form and orthography from the commonly used term, the association of the French, German, and Italian synonyms of important English and Latin names with the prime word, and the system of indicating pronunciation.

In addition to the "Dictionary-portion" of the volumes, a series of useful tables has been prefixed. These consist in tables of doses, poisons and their antidotes, the numbering of spectacle-lenses, tables showing the expectation of life, the relation of the girth of the chest to increasing height, the dimensions and weight of the organs of the human body, and comparative scales giving the equivalent of ordinary weights and measures in those of the metric system, as well as the comparison of thermometric scales. This section closes with the tables of foods and dietaries prepared by Professor W. O. Atwater.

The typography of the work is excellent. Each double-columned page, with its clear type, liberal spacing, and satisfactory indentations is grateful to the eye of him who reads, and a beautiful example of the publishers' wisdom and the printer's art.

Dr. Billings and his collaborators have built a Dictionary for which, without wishing to be unseemingly eulogistic, we have no words but praise. It fulfils all reasonable requirements and meets all sensible expectations. It cannot merely take rank with the standard works of the same character which have preceded it, because it outranks the majority. It at once assumes the position of a model to which all future efforts in a similar line must look for inspiration.

SOCIETY PROCEEDINGS.

M'DOWELL MEDICAL SOCIETY.

Twenty-ninth Semi-annual Meeting, held at Henderson, Kentucky.

MORNING SESSION.

The Society was called to order at 10 A. M., by the President, Dr. John E. Pendleton, of Hartford, Ky.

DR. A. MORGAN VANCE, of Louisville, read a paper on

ANTISEPTIC SURGERY,

in which he said that in the past ten years the great progress of surgery has been in proportion to the increased understanding and confidence in the power of antiseptic and aseptic methods of wound treatment. The day is not far distant when the surgeon will be ashamed to admit the formation of pus in a wound of his making, as he will know that it is from neglect that pus appears. The technique, he said, is to be acquired by reading the medical journals of the day, and making trials of the methods there described.

Dr. Vance then directed the attention of the members to the importance of certain details in the following words:

Don't fail, when possible, to have a general bath before doing a major operation.

Don't do any operation with suspicious hands; hot water, soap, nail-brush, and penknife should be carefully used by the principal and assistants before any operation. It is best to cut the nails very short, so there will be no place for germs to lodge.

Don't, just before or during an operation, put the fingers about your nose, eyes, or ears, or use a handkerchief, or shake hands with any one.

Don't pick up, or allow an assistant to touch, any instrument, sponge, or suture that has fallen to the floor during the operation.

Don't bite off the end of a suture that it may the more easily be threaded.

Don't put a knife or other instrument in the mouth, or behind the ear, preparatory to its use.

Don't cough or sneeze over the operative field.

Don't fail, when possible, to have the patient bathed and clothing changed before an operation. When this is not possible, thoroughly cleanse the field, and never make or dress a wound where the surrounding parts have not been shaved.

Don't allow any visitor to handle the field of operation, after the patient is prepared, unless he is aseptic.

Don't allow visitors who are attending patients with gangrene, erysipelas, or puerperal fever to be present.

Don't fail to have the field of operation surrounded by warm sublimated towels.

DR. I. N. LOVE then made some remarks on the

MANAGEMENT OF FEVERS.

He said that all the cases of fever which come under our observation, after it is well established that they are continued fevers, no matter what the cause, require management rather than medication, though there are times when medication is an important part of the management. In fever cases the first step in treatment should be to clear out the sewers of the patient, keeping open the secretory and excretory organs, by giving full doses of calomel with compound jalap powder, followed by some saline purgative. Sometimes this in itself will overcome the fever, and then proper measures should be taken to prevent its recurrence.

The ice-water and milk given fever patients should have been boiled and kept hermetically sealed in an ice-chest. Cleansing the mouth and teeth are important factors, and no patient with typhoid fever should be allowed to have sordes on the teeth. An item of vital importance is tranquillity of both mind and body. Friends should not be permitted to see fever patients. The physician should insist upon the patient using a bed-pan, and saving muscular effort. With a view to producing this tranquillity, the administration of medicines which produce sleep are of great value. In controlling temperature the speaker highly recommended acetanilid, as he has used it in a large number of cases with very satisfactory results. Given in doses of two and a half grains, every two to four hours, to an adult, it reduces temperature at least one and a half degrees, and keeps it down. The speaker gives it in the form of a solution, with brandy or Tokay wine, which makes an ideal stimulant. He also alternates the sponge-bath with the administration of acetanilid.

Quinine, as an antipyretic, should be ruled out unless there is a malarial element, for the drug disturbs the nervous system and alimentary canal, and impairs digestion and nutrition.

Dr. Love, in closing, favored the pre-digestion of all foods for fever patients for various and obvious reasons, which he gave at considerable length. Bovinine is very satisfactory in such cases, as it is well received, well retained, and is unquestionably very nourishing.

DR. J. E. PENDLETON, of Hartford, Ky., read a paper on

TREPHINING, WITH REPORTS OF CASES,

in which he said that trephining in itself is not a dangerous operation, but that it is usually done for the relief of some injury or pathological condition which either impairs the health or imperils the life of the patient. Operations done for the relief of epilepsy are more nearly fair examples from which to calculate the mortality rate than any other class of cases that have been recorded, but even in these, if the epileptic seizures be due to old traumatisms of the skull, with spiculæ of bone or exostoses impinging upon the brain or its membranes, they should be excluded. It has not been the author's fortune to be called to use the trephine for tumors or epilepsy, and his experience with the instrument has been for the most part confined to recent traumatic injuries of the head. He then reported five cases upon which he had successfully operated.

Dr. Pendleton concluded by saying that though much had been learned and published within the last two decades upon the functions of the cerebral centres, we are not yet in possession of sufficient knowledge to shield us from the danger of making mistakes in locating cerebral lesions. The very complex anatomical arrangement of the nervous centres and their conducting tracts; the facts that two or more areas may be intimately connected with the same function, and that lesions of the same location in different individuals may not produce like definite results, conspire to hinder correct diagnosis. Tumors and abscesses deeply embedded in the brain substance and which would inevitably have destroyed life have been extirpated or evacuated and the patients restored to health. Perilous as may seem these daring ventures in brain surgery, the author said that those cases whose lives are made miserable by constantly recurring fits of epilepsy, and otherwise incurable, will gladly avail themselves of almost any operation to get rid of their malady. In depressed fractures, in subdural hæmorrhage, or in traumatic abscess, if the focal symptoms are of a positive character, there should be no hesitation about operating.

Judging from his own observation and the information he had gathered concerning the conditions of the skull and brain for which trephining may be done, he could only say that the propriety of operating depends chiefly upon our ability to make a correct diagnosis.

Dr. E. H. Luckett, of Owensboro, Ky., read a brief paper on

THE DUTIES OF MOTHERS IN NURSING THEIR CHILDREN.

He said that in investigating the operation of natural laws we cannot fail to observe the mutual relationship and reactions which they produce in their fulfilment, and that this relationship holds good whether they are acting rationally or aberrantly. In no field of their operation is this to be more observed than in the laws regulating biological processes or pathological divergencies. Each law as it applies itself to the development of functional activity in this or that organ is aided by its relationship. In but few organs is this law more beneficently displayed than in the milk glands and the uterus, where the one has for months been caring for a growing, and the other developing for the care of the infant in its independent existence. To set this order ruthlessly at defiance is to invite serious disaster to the woman and greater perils to the child. There is no condition of humanity more to be deplored than that arising from the pathological conditions following childbirth, and among the many causes for these disturbances, failure to nurse stands out boldly and forebodingly. That every mother should nurse her child—except from want of milk or grave disease—will not be gainsaid; it is the demand made by the law of her condition and she cannot shrink from the task or transfer the responsibility without inviting injurious results to herself and taking large chances for physical and mental defects to her child, entailing upon it a puny existence and too frequently an early death. With women who were unable to nurse their children pregnancy might occur every ten to fifteen months, subjecting her to all the mental anxieties, all the nerve perturbations, both reflex and direct, and all the functional derangements incident to the condition almost continually during her sexual life.

Another accident arising frequently in the non-nursing woman is abortion, which is no doubt to a great extent the result of the frequent pregnancies to which such women are subjected. These abortions are fruitful causes of local pelvic troubles, both acute and chronic, and add largely to the list of penalties which women pay for neglect of duty, in discarding the motherly care of their offering.

Dr. Bransford Lewis, of St. Louis, Mo., then read a paper on the

TREATMENT OF GONORRHŒA WITH OINTMENTS,

in which he deprecated the use, in the early stages of gonorrhœa, of astringents, caustics, or other means, antiseptic or otherwise, which would tend in any way to increase the irritation already present, giving as his reason that, aside from the irritation which they produced, they were inefficacious in reaching or killing the gonococci, the morbific agents, because of the location of the latter in the tissues. Admitting the inability to cut short a gonorrhœa in a few days or a week, he had devised a plan of treatment having for its object the conduction of the disease through its several stages as quickly, as comfortably, and as safely as possible, and nothing appeared to him to be more likely to attain these ends than the introduction of a bland ointment, medicated as desired. It is soothing to the inflamed membrane; it keeps the opposing surfaces from rubbing against one another, and in this way obviates all autoirritation. It affords a continuous application of any medicament, with but little trouble to the physician or annoyance to the patient.

Dr. Lewis then exhibited the instrument or applicator which he uses, and described it as a hard-rubber ointment box, fitted at one end with a screw-piston for pressing the ointment out of the other end into a soft-rubber catheter attached. The catheter, having three holes at its end, is a No. 2 French, sufficiently small, smooth, and flexible to glide for a half inch or so into the most sensitive urethra, generally before the patient knows that it is in. The ointment is then squeezed out, pressure being maintained around the glans, so that it is compelled to pass backward over the inflamed area. The catheter is then withdrawn and a muslin hood, lined with clean,

non-absorbent cotton, is placed over the penis, and retains the application until the next urination.

Lately he had been using albolene, an ointment base which is such an inert substance that it neither changes nor becomes rancid with keeping or in combination with medicines. It is odorless and almost tasteless. He prefers it to lanolin because of the qualities mentioned, and is now using it exclusively and with perfect satisfaction.

DR. WILLIAM CHEATHAM, of Louisville, Kentucky, then read a paper entitled

PHLYCTENULAR OR SCROFULOUS OPHTHALMIA,

in which he said that in this disease the hygienic management and the constitutional treatment are of extreme importance, as the most frequent cause of the affection is bad hygiene. As to feeding, all sweets, tea and coffee should be interdicted. Fresh meat should, if possible, be given twice a day, but not at night, and the patient should be kept out of doors as much as possible. In the local treatment of phlyctenular conjunctivitis, frequent washing with carbolized water, hot or cold, as the patient prefers, is of great importance. A solution of two grains of sulphate of atropine in an ounce of distilled water should be dropped into the eye three or four times a day if the inflammation is severe, or if there is photophobia. If dry calomel can be dusted into the eye about noon each day, with a camel's-hair brush, it should be done, or the calomel may be mixed with pulverized white sugar, half and half.

EVENING SESSION.

DR. P. THOMPSON, of Henderson, made some remarks on the

HYGIENIC MANAGEMENT OF THE NEWBORN.

DR. G. FRANK LYDSTON, of Chicago, followed with a paper on the

EVOLUTION OF THE LOCAL VENEREAL DISEASES,

in which he said he was convinced that chancroid and gonorrhœa are diseases which may arise *de novo*, and which are, in the true sense of the term, not specific. It is only by an acceptance of this theory that it is possible to understand something of the origin of those diseases. It may not be possible to demonstrate the origin of all infectious diseases, but it is incomprehensible that a "specific" poison has always existed. The germ theory apparently throws some light upon the origin of infectious diseases. Diseases are incident to the life of every animal, and as we study the evolution of the animal, so should we study the evolution of its diseases.

He believed that the local venereal diseases are the result of the propagation and differentiation of germs primarily innocuous, and that the innocent germs of the atmosphere may multiply in a favorable environment, and the result of such multiplication finally become through successive cultures virulent. Thus the descendants of innocuous germs may have properties which are innocuous or virulent depending upon the environment in which they are developed.

The effects of the germ, even after it enters the tissues of the human being, vary according to (1) its virulency and vitality; (2) the inherent vitality of the individual affected; (3) idiosyncrasy; (4) activity of elimination; (5) the condition of the tissues; (6) the number of germs and length of time of exposure.

The experiments of Pasteur on chicken cholera show conclusively what may be done in the way of modifying germs by proper culture, and is it unreasonable to suppose that such cultivation may occur in nature's laboratory? As a consequence of the great variation in the circumstances controlling the development of germs in the female vagina, the essayist believes that there may result from different inoculations of essentially the same products of evolution different degrees of infection. Thus the disease acquired by exposure to such germs may be a simple balanitis, balano-posthitis or venereal vegetations, simple urethritis, virulent urethritis, simple venereal ulcer indistinguishable from advanced herpes, or, lastly, the true chancroid.

CORRESPONDENCE.

PARIS.

Influenza in Europe; Symptoms; Nature; Contagiousness and Treatment.

To the Editor of THE MEDICAL NEWS,

SIR: Influenza, the interesting disease of the moment, does not seem to be on the decrease in Europe. The reports from all the European capitals indicate, on the contrary, that the number of cases is on the increase, and, what is still more important, that the disease is taking a more severe form. The mortality has apparently doubled and tripled in every city where the disease has shown itself. The real nature of the disease does not seem to have been as yet determined; the greatest medical authorities of Europe are differing on this subject, some believing the affection to be influenza, others considering it dengue fever, while still others admit that the epidemic possesses characters common to both influenza and dengue.

As has been many times stated, the disease was first observed in Russia, where it appeared about the beginning of October. It first occurred in isolated cases, but soon, however, took the form of a true epidemic, which no sanitary measures could prevent. In Russia, the principal symptoms which were observed were as follows:

Most of the patients were taken suddenly, after one or several chills, with a temperature rising to 102° or 104° F. A few moments before this fever, however, the patient usually complained of severe pain in the frontal region. In others, the disease began after several chills, accompanied by a tired feeling, with severe headache, this lasting for twenty-four hours, at the end of which, the temperature reached its highest point.

Again, others felt ill for three or four days, or even a week; they complained of general muscular and intellectual fatigue, great irritability of the nervous system, headache, loss of appetite, sleepiness, etc. Others complained of sore throat of short duration. In young men, the disease usually started abruptly, while in elderly persons there always existed premonitory symptoms. For the first two or three days the patient complained of frontal headache, pain in the muscles of the posterior cervical region, in the sacro-lumbar region, in the legs,

chest, cardiac region, abdominal parietes, or in the articulations. In some, nausea and repeated vomiting have been observed, also delirium. All patients presented more or less depression. Cough presented a convulsive character, dry, or accompanied by mucous expectorations. Most of these cases had the appearance of typhoid fever patients.

In three cases, at one of the St. Petersburg temporary hospitals, a diffused erythema was observed, resembling very much the rash of scarlatina, which, however, disappeared by the second day. In some cases, conjunctivitis, photophobia, and pain in the ocular muscles were noticed. The pharynx was more or less hyperræmic, while the tonsils and sub-maxillary glands were somewhat increased in size. The pulse was small and frequent. In regard to the lungs, bronchitis was observed, but rarely pneumonia. The liver and spleen were found increased in size. A slight amount of albumin in the urine was often discovered. On the third or fourth day the temperature usually fell, and there appeared a more or less profuse perspiration; in about half the cases the temperature went up again on the fourth, fifth, or sixth day, but this febrile state only lasted a day or two, when convalescence would begin.

In Belgium the disease began as elsewhere, by striking collections of people, such as are found in the large stores; in most of these more than two-thirds of the persons were attacked.

M. Renvers, of Berlin, as a result of his recent observations, divides influenza into three clinical varieties: The first is the violent form of the disease, with severe headache, pain throughout the body, and great elevation of temperature. In a few hours the headache becomes extremely painful, the patient complains of nausea, is agitated, face is flushed, and the temperature rises to 104° or 105°. Ten or twelve hours later appear the respiratory symptoms, then profuse sweats, and the disease finally disappears. During the short convalescence there is great fatigue, with pain in the limbs and back.

The second form presents an ascending temperature for one or two days; irregular pains in the limbs, violent cough, dry mouth, etc.; the cough is convulsive, and liable to bring on vomiting. Temperature remains at its maximum for two days, and then gradually descends, but it is from four to five days before all the catarrhal symptoms disappear.

In a third form symptoms appear simultaneously in the organs of respiration and those of digestion. In this form we find a predomination of the nervous symptoms, with loss of appetite. The temperature rises rapidly and the fever may last two or three days. At the beginning these cases resemble typhoid fever.

The complications observed are broncho-pneumonia and fibrinous pneumonia. This pneumonia is peculiar in not presenting rusty sputa nor great cough, but on percussion there is a certain amount of dulness. In some cases erythema of the skin has been observed.

M. Fürbringer, of Berlin, has observed 47 cases of influenza—40 men and 7 women, aged between 16 and 25 years—which is a contradiction of the ordinarily accepted theory that the disease is much more apt to seize elderly people. He has observed fibrinous pneumonia in only two cases, and admits the existence of an abortive broncho-pneumonia only when he finds traces of blood in the sputa. As regards treatment, he thinks the antipyretics useless, as the patients recovered without any active treatment. He does not consider the disease contagious, but rather thinks it a miasmatic disease, due to an organism in suspension in the air.

In Paris, as in the other large cities, the epidemic was first noticed in the largest dry goods store, which employs from 2500 to 3000 employés; the very first day over 300 were taken sick, and in three or four days two-thirds of them were ill. The sanitary physicians who were ordered to examine the character of the disease reported it as being influenza, or grippe. Since then the epidemic has spread over Paris, and markedly increased the mortality for the month of December. The disease in itself is not dangerous, but the mortality is due to the complications to which it gives rise when the patients neglect themselves. As an example of the increase of mortality, during the month of December, 1888, there were 3784 deaths in Paris; during the month of December, 1889, the number of deaths increased to 5969, which gives a difference of 2183 in favor of this year. Examining the statistics in detail, we find that in one week only 22 deaths are reported under the title influenza, while under the head pneumonia, which, in the corresponding week of 1888 gave a mortality of 67 deaths, gives this week 346 deaths; acute bronchitis, which gave 42 deaths, has this year 131; chronic bronchitis, 127 deaths, instead of 47; broncho-pneumonia, 138, instead of 27. The diseases of the respiratory organs have caused a total of 742 deaths, instead of 200, which is the ordinary number at this period of the year. Pulmonary congestion, phthisis, cardiac diseases, hemiplegia, old age—all present a high mortality, certainly due to the existing epidemic.

The question was brought before the Académie de Médecine, where Professor Sée stated that he thought from the result of his observations that the disease was of an infectious nature, having observed in most of the cases that there was an increase in size and a certain tumefaction of the spleen, as is found and observed in typhoid fever and malaria; and he even thinks that the pneumonias which are found as a complication of the influenza are of an infectious nature, as they do not present the ordinary signs of pneumonia—no rusty sputa are observed, very little cough, etc.

Dr. Duiardin Beaumetz states that the present is quite different from preceding epidemics; there are a few new symptoms which are not described as belonging to the disease. The disease begins abruptly, as does dengue fever; persons are taken in the midst of their occupations. In this epidemic two periods are also observed, as in the dengue fever. The first, called the nervous period, presents no catarrhal symptoms, but nausea, vomiting, agitation, even delirium, are observed. The second period resembles very much influenza, and is characterized by a catarrhal fever with mucous-membrane manifestations. Finally, Dr. Dujardin Beaumetz finds another resemblance to dengue fever, namely, the eruption and the physical and moral depression which are present.

The surgeons of the navy, who have had ample opportunity of studying dengue fever in regions where this disease prevails endemically, also find resemblances

between it and the present epidemic. Even those who assert that the present disease is influenza, admit that it is an irregular form.

Professor Grasset, of Montpellier, is ready to admit that the disease is influenza, but a special form of influenza, which brings it very close to dengue fever.

Dr. Corre, of the French navy, although believing that the disease is influenza, yet says that it would not be illogical to admit that it is a hybrid, as the disease has originated in a country where the influenza and dengue prevailed at the same time, and that both these diseases have come to us mixed in different proportions, according to the climatic conditions.

Another surgeon of the navy, Dr. Dangny des Déserts, who has observed the disease on board a naval schoolship, concludes that the disease is not influenza, but an attenuated form of dengue fever. He says that the present disease begins much more like dengue than like influenza. In regard to the eruption, this is always present in severe cases of dengue, but it may be absent in light forms. In 1873 he observed in Cochin China a great many cases of dengue fever, and in a large number of light cases the eruption was absent. During the present epidemic he has seen scarlet eruptions followed by desquamation in several cases. As a conclusion, Dr. des Déserts says that the actual disease not only presents the symptoms of dengue as observed in the colonies in mild cases, but differs from influenza by the fact that coryza and inflammation of the bronchial passages are very often absent.

In Berlin and in St. Petersburg several physicians still hesitate between the nature of the disease. What everyone seems to admit, however, is that the influenza observed at present does not occur with all the classical symptoms usually encountered; it is an abnormal influenza—perhaps even an unknown or not yet described disease.

As regards prognosis, Dr. Dujardin Beaumetz thinks it favorable when a healthy organism is involved, but, on the contrary, very grave when it strikes a broken-down constitution, and in certain cases it will accelerate the fatal termination of an already existing disease.

Certain physicians claim that the rash which has been observed in several cases of influenza was due to the internal administration of antipyrin; Professor Sée and several other practitioners have found the rash only on persons who took quinine.

In certain cases, the complications extend toward the middle ear, causing deafness and otitis; in one case, the inflammation was so great as to produce an inflammation of the mastoid cells, which required trephining of the mastoid process.

At Copenhagen, an unusual complication has been observed; the nasal inflammation which usually announces the disease, extends to the larynx and there becomes so intense, that œdema of the glottis has resulted and several tracheotomies had to be performed.

Great difference of opinion has been expressed as to the contagious character of the disease; the medical societies of Berlin and Paris seem to consider it non-contagious, while certain well-observed facts render its contagious character almost out of question. Professor Grasset, of Montpellier, has obtained the following observation from Dr. Bordone. A gentleman left Paris to go to Frontignan, where he arrived on December 15th, and was immediately taking sick. On the 17th he gave a dinner to which ten persons were invited. On the 19th five out of these ten persons were taken. On the 18th he resumed his work. His second clerk, who resided several miles from Froutignan, was taken on the 21st and remained at home four days. On the fifth day of his disease, his mother, who nursed him, was taken sick. Up to the 15th not one case had been observed, and on December 24th there were 16 cases in Frontignan, and 6 in the neighboring village mentioned above. This certainly proves that the disease is communicable from one person to another.

The best example of contagion, however, is the one reported by Dr. Dangny des Déserts, who is the head surgeon of the naval school ship "La Bretagne," which has a crew of eight hundred and fifty men. From December 14th to January 1st, he has treated two hundred and fourteen patients. Two other naval school ships which are anchored very near, have had no case of the disease; hence the epidemic on board "La Bretagne," cannot be of a climatic nature. The way in which the contagion took place is explained as follows: On December 11th, a naval officer residing in the town, received two large boxes from a grocer in Paris. The boxes contained small cans which were enveloped in wood chips or shavings. Dr. Déserts took them out of the box; three days later he was seized with influenza; the following day, his wife and three servants presented symptoms of the disease. On December 14th this officer, still suffering from the disease, came on board "La Bretagne," where he remained twenty-four hours. On the 17th the epidemic was established, from twenty to forty-five men a day, presenting themselves at the infirmary. All the officers who were permitted to leave the ship, to be treated at their home, communicated the disease to their families.

In regard to the treatment: The usual method adopted seems to be to give the patient a purgative mineral water at the beginning of the attack, while at the same time antipyrin, fifteen grains, is given if the headache is severe, and if the fever is high.

Another treatment has also lately been recommended; this is based on the hypothesis that influenza is an infectious disease; and as the disease, in many cases, has taken an almost strictly abdominal form, intestinal antiseptics such as have been recommended by Professor Bouchard in typhoid fever, are being used.

As soon the patient has the first attack of fever, he must be given every hour four grains of salol, until thirty grains have been administered or even forty-five grains in an adult; three times daily ten grains of naphthalin are given.

In eight cases out of ten, the fever will disappear after the first day of this treatment, which should be continued for four or five days.

Persons or patients who were already taking either salol or naphthol for some other purpose, have very rarely contracted influenza.

The treatment which is recommended by Dr. Dujardin Beaumetz is as follows:

In case, where there exists a great deal of pain, antipyrin and exalgine are the remedies which give the best results. Thirty to forty-five grains of antipyrin are adminis-

tered in a hot punch or in tea and rum. The following formula he recommends for the use of exalgine:

R.—Exalgine	37½ grains.
Tinct. of peppermint . . .	℥ijss.
Syrup of orange flowers . .	℥j.
Water	℥iv.—M.

A teaspoonful every morning and evening. If there there is periodical fever, quinine is to be used, four grains of the hydrochlorate morning and evening.

In the catarrhal form, he recommends tincture of aconite, taken three times a day as follows:

In a cup of milk put two tablespoonfuls of sirup of tolu; one teaspoonful of cherry laurel water; ten drops of the French tincture of aconite root. This mixture to be given three times a day. As a continuous drink for the patient tea seems to be best supported.

Of course, if the febrile, painful or catarrhal forms of the disease, are associated, the above mentioned drugs should be combined accordingly.

THE MEDICAL SOCIETY OF SOUTH CAROLINA.

To the Editor of THE MEDICAL NEWS,

SIR: On the 9th day of December, 1889, the Medical Society of South Carolina celebrated its one hundredth birthday. This Society is the third oldest medical society in the United States, it being antedated by that of Massachusetts and the College of Physicians of Philadelphia. Among its founders was David Ramsay, the noted physician and historian, who was a native of Pennsylvania, and one of the earliest, if not the first graduate from the University of Pennsylvania. This Society has always held an honored position in South Carolina, and many of her sons have been known not only throughout this country but in Europe. For many years her members constituted the Board of Health, and were always consulted by the city authorities upon all sanitary matters. In 1724 the Society obtained from the General Assembly a charter for a medical college—the original medical college of this State—the Medical College of South Carolina. The professors were chosen from the members of the Society, and students applying for their degrees were examined before and by members, and the degrees were conferred by the Society. Finally, a controversy arose between the professors and the Society, which ended in the former resigning their chairs, obtaining a charter for a new college, called the Medical College of the State of South Carolina. This prospered, and though the Society filled the vacant chairs of the original college with bright minds from at home and abroad, its day was over, and it finally succumbed, leaving the new College in a flourishing condition. From it many eminent men have been graduated, and it is still pursuing its mission.

The Society celebrated its centennial by an oration which was delivered by Dr. Cornelius Kollock, of Cheraw, S. C., and afterward adjourned to partake of a handsome banquet at the Charleston Hotel.

The Roper Hospital, supported by the Roper Fund, for which the members of the Society are the trustees, is being repaired after the damages caused by the earthquake, and will, in all probability, be opened at no very distant date.

The officers of the Society for the ensuing year are as follows: President, T. Grange Simons, M.D.; Vice-President, R. L. Brodie, M.D.; Treasurer, J. L. Dawson, Jr., M.D.; Secretary, Charles M. Rees, M.D.; Librarian, Walter P. Porcher, M.D.

ST. PAUL AND MINNEAPOLIS.

To the Editor of THE MEDICAL NEWS,

SIR: There have not been many events of interest in a medical way in St. Paul or Minneapolis lately.

Dr. Vincent J. Hawkins, of St. Paul, has performed a Cæsarean section upon a dwarf, and both mother and child are alive and well.

The patient was seventeen years of age, 3 feet 5 inches tall, measured 30 inches around the hips and weighed 55 pounds. The conjugate diameters were 1¼ inches, the lateral diameter 3¼ inches.

The operation was begun two hours after the onset of labor pains and was performed in the usual manner, with antiseptic precautions. The patient suffered from collapse during the first twenty-four hours, and the highest temperature was reached on the fifth day; from this time she made an uninterrupted recovery.

The Medical Department of the University of Minnesota has started out with a class of eighty-seven students, and is flourishing.

Dr. Van der Horck, of Minneapolis, has under his care two cases of leprosy of the tuberculous variety; they are both Swedes; the older one is totally blind and suffering from tuberculosis of the lung.

It may interest the graduates of Jefferson Medical College to know that our State Board of Examiners has refused graduates of that school admission to our State examinations for license to practise medicine in Minnesota, on account of the shortness of the course of study. Our State law requires that to be eligible for examination, the candidate must be a graduate of a medical school having a graded course of at least three sessions of six months each.

A CORRECTION.

To the Editor of THE MEDICAL NEWS,

SIR: In looking over an article "Three Cases of Appendicitis; Operation; Recovery," by J. M. Baldy, M.D., of Philadelphia, which appeared in THE MEDICAL NEWS for November 23, 1889, I notice that on page 580 he makes the following remark: "In this case (mentioning my name) the appendix itself, after being freed from its adhesions, was allowed to remain, it being considered healthy enough to do no harm." Dr. Baldy must certainly have forgotten the operation, for the *appendix was ligated and cut off*, and moreover I have the *identical appendix in a bottle of alcohol* in my office.

Yours truly,

EUGENE P. BERNARDY.

NEWS ITEMS.

Regulations of the Tenth International Medical Congress — The following are the more important regulations of the Tenth International Congress:

I. The Tenth International Medical Congress will be opened in Berlin on Monday, August 4, 1890, and will be closed on Saturday, August 9th.

II. The Congress shall consist of legally-qualified medical men who have inscribed themselves as members, and have paid for their card of membership. Other men of science who interest themselves in the work of the Congress may be admitted as extraordinary members.

Those who take part in the Congress shall pay a subscription of twenty marks (five dollars) on being enrolled as members. For this sum they shall receive a copy of the *Transactions*, as soon as they appear. The enrolment shall take place at the beginning of the Congress. Gentlemen may, however, be enrolled as members by sending the amount of the subscription to the Treasurer,[1] with their name, professional status, and residence appended.

III. The object of the Congress is an exclusively scientific one.

IV. The work of the Congress will be discharged by eighteen different Sections. The members shall declare, upon enrolment, to which section or sections they intend more particularly to attach themselves.

V. . . . . .

On account of the different languages employed, a suitable number of secretaries shall be chosen from among the foreign members. The duties of the foreign secretaries shall be confined to the sittings of the Congress.

After the termination of the Congress, the editing of the *Transactions* shall be carried out by a committee specially appointed for this purpose.

VI. The Congress will assemble daily, either for a general meeting or for the work of the different sections. The general meetings will be held between 11 and 2 o'clock. Three such meetings will take place.

VII. The general meetings shall be devoted to (*a*) transactions connected with the work and general management of the Congress; (*b*) speeches and communications of general interest.

VIII. Addresses in the general sittings, as well as in any extraordinary meetings which may be determined upon, can only be given by those who have been specially requested by the Committee of Organization.

Proposals relative to the future management of the Congress must be announced to the Committee of Organization before July 1, 1890. The Committee shall decide whether these proposals are suitable to be introduced for discussion.

IX. In the sittings of the sections, questions and problems will be discussed, which have been agreed upon by the special committees of organization. The communications of those appointed by the committee to report on a subject shall form the basis of discussion. As far as time allows, other communications or proposals proceeding from members, and sanctioned by the Committee of Organization, may also be introduced for discussion. The bureau of each section decides as to the acceptance of such offered communications, and as to the order in which they shall come before the meeting, always provided that this point has not been already determined in the sitting itself by a decree of the section.

Scientific questions shall not be put to the vote.

X. Introductory addresses in the sections must, as a rule, not exceed twenty minutes in length. In the discussions no more than ten minutes are allowed to each speaker.

XI. All addresses and papers in the general and sectional meetings must be handed over to the secretaries, in writing, before the end of the sitting. The Editorial Committee shall decide whether, and to what extent, these contributions shall be included in the printed *Transactions* of the Congress. The members who have taken part in the discussions will be requested to hand over to the secretaries, before the end of the day, in writing, the substance of their remarks.

XII. The official languages of all the sittings shall be German, English, and French.

XIII. The acting president shall conduct the business of each meeting according to parliamentary rules.

XIV. Medical students, and other persons, ladies and gentlemen, who are not physicians, but who take a special interest in the work of a particular sitting, may be invited by the president or be allowed to attend the sitting by special permission.

XV. Communications or inquiries regarding the business of separate sections, must be addressed to the managing members thereof. All other communications and inquiries must be directed to the General Secretary, Dr. Lassar, Berlin N.W., 19 Karlstrasse.

[1] Treasurer's address: Dr. M. Bartels, Berlin S.W., Leipsigerstrasse 75. Please enclose a visiting-card.

Hydrophobia from the Bite of a Cat.—Principal Clark, of the Albion Academy, at Milton, Wisconsin, is reported to have died from hydrophobia, resulting from the bite of a cat ten months previously. The immediate effects of the bite appeared to be trivial, but the hydrophobic symptoms, when they declared themselves recently, were unmistakable and death most painful.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 28 TO FEBRUARY 3, 1890.

By direction of the Secretary of War, the extension of leave of absence granted C. N. BERKELEY MACAULEY, *Captain and Assistant Surgeon*, in S. O. 294, A. G. O., December 18, 1889, is further extended one month.—Par. 1, *S. O. 22, A. G. O.*, January 27, 1890.

MIDDLETON, JOHNSON V. D., *Major and Surgeon.*—Is granted leave of absence for fifteen days.—Par. 9, *S. O. 21, Headquarters of the Army, A. G. O.*, January 25, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING FEBRUARY 1, 1890.

RUSH, C. W., *Passed Assistant Surgeon.*—Detached from the Naval Academy, and placed on waiting orders.

DECKER, C. J., *Assistant Surgeon.*—Ordered to the Naval Academy, February 1st.

GREEN, E. H., *Passed Assistant Surgeon.*—Detached from the "Alert," and placed on waiting orders.

BEARDSLEY, G. S., *Medical Inspector.*—Granted extension of leave to April 30th, with permission to remain abroad.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1007 Walnut Street, Philadelphia.*

VOL. LVI. SATURDAY, FEBRUARY 15, 1890. No 7.

ORIGINAL LECTURES.

ANEURISM OF THE AORTA.

A Clinical Lecture.

BY RICHARD LEA MACDONNELL, B.A., M.D.,
PROFESSOR OF CLINICAL MEDICINE IN THE MCGILL UNIVERSITY;
PHYSICIAN TO THE MONTREAL GENERAL HOSPITAL.

GENTLEMEN: Within the last month we have had opportunities for studying the clinical features presented in two cases, both of which are believed to be suffering from thoracic aneurism. One, you will remember, is our own patient, the other man came from the service of Dr. Molson, who very kindly sent him to us for purposes of examination.

This man, whom you have seen almost daily for the last month, came to us from the throat department of the hospital, a department which frequently introduces to us our aneurism patients. The man is forty-four years old, a railway laborer, and it is very probable that he has had syphilis. At least, we cannot exclude syphilis from our consideration. He confesses to having had gonorrhœa and a soft chancre four years ago. As we cannot depend upon his differential diagnosis of chancre from chancroid, we cannot, therefore, assert that there is no history of syphilis.

The three points thus far given represent the three important factors in the production of aortic aneurism: 1, age; 2, occupation; 3, history of syphilis.

The age at which aneurism of the aorta usually appears is not that of youth, nor yet that of old age, but an intermediate stage; the time when a man is beginning to get structurally old, at the same time that, in a muscular sense, he is still young. The strain which the vessels can bear when they are young and elastic will cause them to stretch and break when they are old and less resilient. A potent agent in producing arterial degeneration is syphilis. Normal senile changes *plus* syphilis render an artery fragile long before its time. The patient is more conscious that he is becoming old, or that hard muscular work is not suited to him. The strain goes on, the weak artery offers less and less resistance to the blood-current, a stretching occurs which increases with greater or less rapidity until symptoms of pressure on neighboring organs begin to be apparent. The case is diagnosed, and the treatment, based on the knowledge of the causation, is instituted; symptoms are usually relieved, and the progressive enlargement of the aneurism is often arrested.

Aneurisms are caused either by local weakness of the arterial wall, or by repeated sudden increase in the blood-tension. Localized weakness in the arterial wall is caused by chronic endarteritis, but degeneration of any of the three coats produces a weakened condition of the wall which allows of its being forced outward by the heightened pressure within. The middle coat is the one most commonly involved, and it is thought that in all cases this coat has given way. Syphilis produces an arteritis of the middle coat, hence the frequency with which a history of syphilis is met with in our aneurism cases. Increase in blood-pressure, which is sudden and repeated, is more dangerous than that which is steadily acting, for we do not often find aneurism in cases of a chronic nephritis where we know that there is increased blood-pressure. There are instances, too, where an aneurism is supposed to date from one particular strain, as, for example, in one of my cases where the patient attributed the disease to his effort in lifting a large lump of ice; and we know, too, that many patients say that their aneurism resulted from an injury. Thus a man who was in the hospital two years ago said that his aneurism was the result of the kick of a horse. I do not think the kick itself produced the aneurism, but it is probable that the effort made by the patient to avoid the injury caused a sudden increase of blood-tension which resulted in the initial bulging of the aorta.

The disease usually occurs amongst those who follow a laborious life, but this is not always the case. One of my patients had been a barber all his life, another a commercial man. I am inclined to think that the excessive use of the arms strongly predisposes. One of our hospital patients had been an instructor in sword exercise in the cavalry, and had worked a great deal as a chopper. That the disease is very common amongst soldiers is beyond doubt, but then it must be remembered that in soldiers a history of syphilis and alcoholism is very commonly met with. I doubt if it will be found amongst the soldiers who are serving on the present short service plan. The old-fashioned soldier was very fond of drink, seldom escaped venereal disease, and was kept in the ranks for a very long period, getting his discharge at a time of life when he was too old for the manual labor which remained as his only means of getting a living. Tight-fitting dress and accoutrements are also thought to have aided in the production of aneurism.

The favorite site of an aneurism is either in the ascending part of the arch of the aorta, or, more commonly, the junction of the ascending and the transverse portions of the arch.

Usually the walls of an aneurism are composed of the outer and inner coats of the vessel; the middle coat can be found, usually much thinned, just at the neck of the sac where it is continuous with the middle coat of the sound part of the artery. The fibrin deposited from the blood is generally found in layers on the inside of the aneurism deposited one upon another like the layers of an onion.

Our patient began eight months ago somewhat suddenly to suffer from difficulty in breathing after exertion, and whenever he attempted to undertake any heavy work the sensation of choking became so urgent that he

was obliged to desist. A cough came on at the same time, and he says that he brought up a great deal of phlegm. A thoracic aneurism produces by its pressure an irritative tracheitis, which often gives rise to a great deal of expectoration.

These symptoms were present for two months before any pain in the chest was experienced. There was pain continually present in the upper part of the chest, but it did not shoot into his arms at any time. This pain is not now so severe as it was, and it is noticeable in cases of aneurism that the pain is usually more severe at the outset of the disease. This can be accounted for by the fact that the pain is caused by pressure upon neighboring structures, which, at first, resent the presence of the encroaching swelling. After a time the parts accommodate themselves to the altered relationship of the thoracic contents. I well remember the case of a clerk, who, by the way, had been a soldier, and had had syphilis, in whom the pain resulting from a supposed innominate aneurism had been most intense, almost anginal. Here sudden relief was obtained by the forward dislocation of the right clavicle.

To return to our patient, he also complained that in swallowing he felt a sharp, smarting pain beneath the sternum, which was very much more severe whenever cold fluids were taken.

There has never been any hæmoptysis. Latterly, the voice has been hoarse and the cough very troublesome. He applied for relief at the throat department, where Dr. Major discovered paralysis of the left vocal cord, diagnosed aneurism, and sent him to the wards for treatment.

To recapitulate: Here is a man of forty-four, a laborer, with a history of syphilis, who is suffering from a chronic affection, of which the symptoms distinctly complained of are: dyspnœa on exertion, distressing cough, a suffocating sensation in his chest, severe continuous pain in the upper part of the chest, and dysphagia, symptoms pointing unmistakably in the direction of thoracic aneurism.

Before we had time to look into the history which the clinical clerk had carefully prepared, before we had time to examine his chest, he himself made a diagnosis. You will remember that, at a previous clinic, I immediately called the attention of the student, whom I had requested to examine the case, to the cough, and asked him if he noticed any striking peculiarity in it. That cough was distinctly the cough of aneurism, a loud ringing, more than ringing, a clanging cough, which was frequent, and came in paroxysms. It occurred several times in a few minutes, and was most distressing. I have known an aneurism to be diagnosed merely by that peculiar clanging cough heard through the thin partition separating the cabins in an ocean steamer.

Now for the appearance of the patient. He was by no means emaciated, and, but for the distressing attacks of coughing, one would suppose that he was in the most robust health. He told me, a few days ago, that he had failed to obtain any sympathy on account of his healthy appearance. Examining him closely you see that he is older than his years. His hair is very gray, and he might easily pass for a man not far from sixty. Now what evidences of aneurism can we make out before we give our attention to the physical examination of the chest?

First. *Aphonia.* He answers questions in a hoarse whisper, and attempts at speech bring on severe attacks of coughing.

Second. *Pain.* He says that he suffers from pain, both across and through the chest, sometimes dull, sometimes stabbing. This latter sensation is referred to a spot between the shoulders.

Third. *Dysphagia*, which has been constantly present for the last four months.

Fourth. The left pupil is smaller than the right.

Now, when he is stripped, we examine the chest very closely, and perceive no undue prominence upon any part of the chest-wall, and that the heart's apex is beating in its usual position. Palpation carries us several steps further in our diagnosis. We palpate behind the episternal notch, but there is no tumor to be felt there. We feel the trachea and find that at every beat of the heart the larynx is pulled down toward the sternum. More than that, if the forefinger be placed on the *pomum Adami* so as to exert gentle continuous pressure upward, the cardiac pulsations can be distinctly counted, and the number corresponds with that counted at the radial artery.

Percussion enables us to say that the extent of cardiac dulness is not enlarged. There is dulness over an area, bounded above by the clavicle, internally by the median line, externally by a line dropped from a point on the clavicle two inches to the left of the sterno-clavicular articulation, and below by the lower margin of the second rib. There is no dulness posteriorly.

The stethoscope fails to detect any abnormal heart-sound, but when it is placed over the dull area a marked systolic bruit is heard, and this bruit is intensified when the patient sits up. It is not audible in any other part of the chest. There is harshness of breathing all over both sides of the chest, but this is more marked on the left side. The pulse is 63 per minute, but on the left side it is almost imperceptible at the wrist.

Let us sum up now the symptoms and physical signs which our examination has afforded us: 1. Cough or dyspnœa on exertion, with suffocative sensations in the chest. 2. Pain in the chest. 3. Dysphagia. 4. Discomfort on lying on the right side. 5. Contracted pupil on the side on which the tumor is supposed to exist. 6. Trachael tugging. 7. Dulness on percussion over the part of the chest thought to be prominent. 8. Systolic bruit.

Can we locate the tumor? Remember what I have so often told you in the dissecting-room, that the transverse portion of the arch runs almost directly from before backward, and that the structures which are said to lie in front really lie at the left side of the arch. In this patient there is dulness at the left of the manubrium sterni; the aneurism is bulging in that direction. Possibly it presses upon the left phrenic nerve, but it lies between it and the soft lung, so that probably its function is not interfered with. Then the trunk of the left vagus may for the same reason escape, but its recurrent branch must appreciate even a slight change in the calibre of the arch, for it winds around it and takes its upward course between the arch and the trachea, two hard bodies which are very likely to squeeze it, as they undoubtedly do in this case. The respiratory sounds in the left lung and the large amount of expectoration with occasional bloody streaks, lead me to suppose that the left

apex is compressed. The parts at the right side (or posterior side) of the arch all give evidence that they are subject to pressure. Apart from hoarseness and cough there is evidence of pressure on the fork of the trachea or upon the bronchus by the presence of tracheal tugging, which is better marked in this case than in any I have seen. When this sign is present it means distinctly that the tumor is attached to the trachea or bronchus, and inasmuch as there is pulsation in it, it also means that consolidation has not been effected.

If you direct your attention to the relations of the æsophagus you will see how pressure upon that collapsible tube is not readily brought to bear. It is between the trachea and the vertebral column, and would be likely to be pushed against the pleura of the opposite side of the chest if the aorta were to enlarge in that direction. Dysphagia is often absent in cases where a tumor even of considerable size occupies the chest.

The patient complained that he felt choked whenever he attempted to lie upon the right side. The reason for that is plain. The tumor lies to the left side of the trachea, and when he lies upon his right side the weight of the tumor comes upon his trachea and increases the pressure on the recurrent laryngeal nerve. The thoracic duct, which lies on the left front of the vertebral column, is a small tube, and likely to slip out of the way should the aorta enlarge so as to squeeze it against the spinal column. Lastly, you must bear in mind that the upper part of the thorax is very narrow from before backward. There are not two inches between the top of the sternum and the spine. A tumor as large as a hen's egg would exert pressure both on the sternum and on the vertebræ and adjacent ribs.

TREATMENT OF TUBERCULOSIS.

By J. LEWIS SMITH, M.D.,
OF NEW YORK.

(Concluded from p. 651, Vol. lv.)

Curative Treatment.—It has long been the belief in the profession, as well as among the laity, that tuberculosis is in the end, with few exceptions, fatal, whatever remedial measures are employed; and that, therefore, remedies may ameliorate symptoms, but do not change the result. But since attention has been directed to this subject, a sufficient number of observations have been made to show that tuberculosis, at an early stage, can in a large proportion of cases be cured or rendered latent. The late Professor Austin Flint, in his treatise on *Phthisis*, published in 1875, stated that of 670 phthisical cases which came under his observation, he ascertained by auscultation and percussion that the disease had been cured in 44, and was non-progressive in 31 others. But the most convincing proof of the curability of tuberculosis is furnished by the post-mortem examination of those who have died of other diseases. A cretaceous or fibroid state of the apex of the lung, without tubercles elsewhere, may be regarded as certain evidence of arrested tuberculosis. Now, two of the curators of large New York hospitals inform me that they frequently find cretaceous or fibroid degeneration at the apex of the lung without tubercles elsewhere, in the autopsies in these institutions. One of these gentlemen, whose examinations are in the dead-house of Bellevue Hospital, states that this evidence of arrested tuberculosis is present in at least one-fourth of the cadavers which he examines, and the Bellevue Hospital patients come from the most crowded and insalubrious tenement houses of the city and have led a life of poverty and privation, and frequently of dissipation. The London *Lancet*, September 22, 1888, states that M. Vibert has examined the records of the necropsies in the Paris morgue, and that in 131 subjects whose death had been sudden from violence or acute diseases, the lesions of pulmonary tuberculosis were present in 25, and in 17 of these the tubercles had undergone the cretaceous or fibroid change, and were practically cured. It is certain, therefore, that tuberculosis of the adult in its commencement, and when affecting only a small portion of the lung, is often cured or rendered permanently latent.

Professor Prudden, of the Laboratory of the College of Physicians and Surgeons, informs me that ordinary serum circulating in the bloodvessels possesses marked germicidal properties, and therefore measures which benefit the general health and improve the quality of this important constituent of the blood, have a curative effect as regards tuberculosis. The tubercle bacillus is an irritant to the tissues, and in cases which are cured or rendered latent it becomes surrounded by dense tissue, which in time undergoes the cretaceous or fibroid degeneration. The bacilli in the interior of the mass may retain their vitality for an indefinite time, but being encapsulated they do no harm. There can be no doubt that many adults have local tuberculosis, and are cured by improvement in their general health and in the quality of their blood, without suspecting that they have had this disease. In young children, especially in infants, tubercles are frequently disseminated in the organs, and recovery under such circumstances must be impossible or rare; but local tuberculosis or tuberculosis limited to certain glands, as the bronchial, is not unusual in childhood, and this form of the tubercular disease may be cured by measures which improve the general health.

The indications of treatment of tuberculosis are twofold: first, to invigorate the system in every possible way, so that the organs and tissues are in a better condition to resist the bacillus and the serum to antagonize and destroy it; and, secondly, the employment of medicinal agents, if such can be found, which are destructive to the bacillus and safe to the patient.

Measures designed to improve the general health must be chiefly hygienic, and are described in all the text-books. The diet should consist of milk, the meat preparations, and farinaceous substances, prepared in such a way that they afford the maximum amount of nutriment and are easily digested. If the digestion be poor, peptonized food may be advantageously employed, and pepsin may be taken with the food. In 1881–82 Debove recommended gavage or forced feeding of consumptives through a flexible rubber tube, having a funnel attachment, the tube being introduced into the stomach. He employed meat preparations, with pepsin. In THE MEDICAL NEWS, October 1, 1887, Dr. S. Solis-Cohen, of Philadelphia, also recommended gavage in the treatment of phthisis. A quart of milk, two tablespoonfuls of beef powder, three eggs, fifteen grains of scale pepsin, and thirty drops of dilute muriatic acid were warmed and administered twice daily through a stomach tube, a patient eating what he wished in the interval. Gavage has been employed by certain European physicians in the treatment of children suffering from various forms of innutrition, and it seems probable that tubercular patients may be benefited by it in some instances. In the ordinary mode of feeding, the predigested foods can often be used with benefit by consumptives, inasmuch as they have, for the most part, feeble digestion.

As regards the hygienic measures designed to arrest tuberculosis, the most important, next to the use of proper food and the employment of such aids to nutrition as cod-liver oil and the alcoholic preparations, is outdoor life, and, if possible, in localities having a high altitude. The late Professor Flint, in examining the records of 62 cases of arrested phthisis which came under his observation, ascertained that the principal agent in effecting this result was exercise in the open air. He therefore strongly recommended this mode of life to consumptives, and also constant ventilation of their sleeping apartments, even in the winter season, the danger of taking cold being averted by maintaining sufficient warmth of air by a fire. Dr. James Blake has also reported instances of recovery of phthisical patients who lived, during the five or six months of the dry season, in the open air upon the coast range of mountains in California at an altitude of 3000 to 5000 feet. These patients were in the open air night and day, without even the protection of tents.

Residence at a High Altitude.—The London *Lancet*, May 26, 1888, contains the abstract of a paper read before the Medico-Chirurgical Society of London by Dr. Williams, recommending residence at a high altitude as an efficient means of checking the progress of tuberculosis. He states that of 141 patients who had employed the high altitude treatment, 14.13 per cent. were completely cured, 29.78 per cent. were much benefited, 11.34 per cent. were more or less benefited, and 17.02 per cent., including 13.47 per cent. who died, continued to grow worse. Drs. Quain and Pollock, in discussing this paper, expressed the opinion that consumptives who improve at high altitudes, improve equally with the same treatment at lower elevations; in other words, that residence at a high altitude does not influence the result. Brehmer, on the other hand, believes that the inhabitants have immunity from tuberculosis at an altitude of 1500 feet in Germany, of 4500 to 5000 feet in Switzerland, and 10,000 to 15,000 feet at the equator (*Die Therapie Chronische Lungenbeschwerden*, Wiesb., 1887). The most apparent and notable peculiarity in the air at high elevations, apart from its purity, is its rarefaction. At an altitude of 9000 feet above the level of the sea, it is said from observations made, that the air is so rarefied that three times the usual exercise of the lungs is required to meet the demands of the system. Dr. Mays states in a paper published in THE MEDICAL NEWS, November 27, 1886, that the Quichua Indians, on the lofty plateaus of Peru, constantly breathing a rarefied air, "acquire enormous dimensions" of the chest, due to an increase in the size and perhaps number of the air cells. More numerous and more exact observations are required in order to determine whether, or to what extent, residence at a high altitude is beneficial to consumptives, and if it exerts a controling effect on the disease, whether this result is due to the increased pulmonary expansion and activity or to other causes. Certainly, from observations already made, we are justified in recommending outdoor life in a mild and equable climate, and also residence at high elevations if the cold is not too severe.

Residence in the Evergreen Forests, and the Use of Turpentine.—In an interesting paper read before one of the societies, and subsequently published, Dr. A. L. Loomis states his belief that the terebinthinate vapors in the evergreen forests possess healing properties for consumptives. He quotes the statement of Ringer that turpentine employed as a medicine enters the blood, and may be detected in the breath, the perspiration, and in an altered form in the urine of the patient. The presence of the vapor of turpentine in the pine forests, Dr. Loomis remarks, cannot be doubted, and its "local and constitutional effects," he adds, "are those of a powerful germicide as well as stimulant" Dr. Loomis quotes the opinion of Mr. Kingsett that turpentine, during its oxidation, evolves the peroxide of hydrogen, and therefore by the "oxidation of the terebinthinates, there is produced in extensive pine forests an almost illimitable amount of peroxide of hydrogen, which

renders the atmospheres of such forests antiseptic." He believes that the peroxide of hydrogen so abundantly produced in pine forests "successfully arrests putrefactive processes and septic poisoning," and therefore he recommends residence in the pine forests as one of the most efficient means of relieving the symptoms of tuberculosis and retarding the progress of this fatal malady. At high altitudes, the coniferous or evergreen trees usually predominate, and if the views of Professor Loomis be substantiated by future investigations, it may be that the benefit believed to be obtained by consumptives at high elevations is partly due to the exhalations from these trees.

The bacteriologists who have cultivated the tubercle bacillus, and observed the action upon it of the various agents which have been employed and extolled by clinical observers, state that most of these agents do not penetrate the tubercular mass; that while they may destroy the superficial bacilli, they do not affect those more deeply seated, and therefore fail to arrest the disease. But turpentine and its derivatives appear to penetrate the tissues as deeply as almost any other agent, and therefore if they are sufficiently antiseptic and not too irritating, we may expect good results from their judicious use. But it is probable that they are less efficient as germicides than some of the other agents which can be safely employed, and therefore should be recommended only as adjuvants, or as remedies which may give some relief to the catarrhal and other symptoms without exerting any marked antiseptic action. Hohnfeld states that he applied oil of turpentine to fresh colonies of the micrococcus prodigiosus and staphylococcus aureus, and that it exerted little destructive or retarding effect on these microörganisms.[1] These experiments would lead us to distrust the germicide action of turpentine and the terebinthinate preparations in tuberculosis, for the tubercle bacillus is tenacious of life beyond most other microbes. But the alleged good results of teaspoonful doses of the oil of turpentine in that other fatal microbic disease, diphtheria, certainly justify the experimental use of this agent in tuberculosis.

Terebene, produced by the action of gaseous hydrochloric acid on turpentine, has been prescribed in tuberculosis and chronic bronchial catarrhs, with some apparent benefit. An adult should take ten increased to twenty drops three times daily. A child can take a dose proportionate to the age. The following formula has been recommended:

℞.—Terebene . . . . . ℥iv.
Pulv. acaciæ . . . . . ℥iij.
Aquæ . . . . . ℥ij.
Syr. zingiberis . . . . . ℥j.—M.
Dose, one teaspoonful.

[1] Fortschritte der Medicin, October 1, 1887.

Terebene can also be employed by inhalation from Robinson's inhaler, or, properly diluted, from the hand or steam atomizer. It has been administered in ten drop doses to some of the consumptives in my wards in the Charity Hospital, and the resident physician who had charge of these cases writes to me as follows

"I am satisfied that in nearly all cases of dyspnœa it is of value. In some it affords marked relief, and I have had patients tell me that it gave the most relief of anything. Others say that it afforded some relief. It makes expectoration in some patients markedly more easy, and the sputum much thinner; in others the effect is only slight or moderate."

It probably aids in relieving the catarrh which accompanies tuberculosis.

Hot Air Inhalations.—Halter states that workers in a limekiln, breathing dry air at a temperature of 122° to 156° F., were exempt from phthisis during a period of fifteen years, in a locality where this disease was common. He also states that the most favorable temperature for the growth of the bacilli is 98.6° to 104° F., and that a temperature of 105.8° destroys them. Moreover, his experiments have shown him that the inhalation of dry air at a temperature of 248° to 256° raises the temperature of the expired air to about 109.7°, a degree of heat which, he says, is fatal to the bacillus.[1] Dr. E. Krull states that for more than two years he has treated consumptives with the inhalation of hot air heated to 132° F., and that this raised the temperature of the expired air to not less than 107.6°, and incipient cases seemed to derive benefit from this treatment. Dr. Weigert, of Berlin, has constructed an apparatus for the inhalation of hot air, which was employed for a time in the wards of Charity Hospital, but it did not seem to give as much relief as the antiseptic inhalations which have been used by the same patients.

Dr. Trudeau, of Saranac Lake, prescribed the hot air treatment in four cases, four hours each day, the temperature of the inhaled air being 392° F. The first and second patients improved slightly at first, but refused the treatment, the one after one month, and the other after six weeks. The third patient was treated three months without the least appreciable effect. The fourth patient was treated four months, with manifest improvement in her physical signs and general health, but no more improvement than frequently occurs from any new mode of treatment. In all the cases the sputum was examined before, during, and after the treatment, and in every examination the tubercle bacillus was present. The result claimed for the hot air treatment had not been obtained—that is, the destruction of the bacilli; and if they are not destroyed in the sputum, certainly they are not in the tissue of the lung. Therefore

[1] Berliner klinische Wochenschrift, September 3, 1888.

there can be little doubt that the hot air inhalations, so far from coming into general use, will be discarded, not only because they are unpleasant to the patient but are inefficient. There is always a large amount of residual air in the alveoli, and there can be little doubt that in the hot air inhalations the air in the alveoli and terminal bronchial tubes never attains the elevation of temperature of the air that is inhaled, nor of that which is exhaled. Moreover, as we have seen, the tubercle bacillus resists the destructive action of high temperature. It is said to retain its vitality in liquids which have been twice heated to the boiling point.

Creasote.—Of the many medicines which have been recently employed in the treatment of tuberculosis, creasotè appears to have given more general satisfaction than any other. I am informed that the late Dr. Cammann, the inventor of the binaural stethoscope, employed it twenty years ago in the treatment of tuberculosis, but it was seldom prescribed for this disease until within the last decade. In the *Berliner klinische Wochenschrift*, July 20, 1886, von Brunn states that he has treated 1700 phthisical patients in the last eight years with creasote, giving to adults not less than six to eight drops in twenty-four hours. He employed it in solution with tincture of gentian and wine, and believes that he obtained good results, especially in acute unilateral cases. Professor Sommerbrodt states[1] that he employed creasote in about 5000 phthisical cases during the preceding nine years. At first he used Bouchard's solution of creasote, and afterward gelatine capsules, each containing three-fourths of a grain of creasote and three minims of the balsam of Tolu. The amount of creasote administered daily to the patients who were adults was increased gradually from one capsule to not less than nine. As many as 600 to 2000 capsules were given to each patient without a break. In many cases the improvement was marked, not only in the symptoms and in the general health but also in the physical signs. He believes that he has cured cases by insisting on a continuance of the treatment. To show the good effects of creasote, he cites the case of a student of sixteen years, with tuberculosis of the right lung, who took three capsules three times daily, or about seven and and a half grains per diem. His cough abated, his weight increased six pounds in two months, his expectoration had ceased. Instead of the dull percussion sound over the apex of the right lung, only a slight rhonchus was observed and his general health had greatly improved.

Many others who have employed creasote during the last two or three years, both in this country and in Europe, report favorable results. Strümpell says that it produces no ill effects, and in large doses it frequently causes improvement in such symptoms as the cough, expectoration, and appetite, but he doubts whether it exerts any marked curative effect upon the disease. It has been employed during the last year in Charity Hospital, and the resident physician who had charge of the ward in which it was used writes to me that it "Seems to possess some staying influence over the progress of the disease." In the New York Foundling Asylum creasote in cod-liver oil has been administered during the last year to the few phthisical patients under treatment in doses of one drop three or four times daily to children of three or four years, and Dr. Lynde, the resident physician, thinks that it has been the most useful of the remedies employed.

During the past year, I have prescribed creasote for internal use in the following formula:

R.—Creasoti (Morson's) }
Spiriti chloroformi } . . āā ℥ss.—M.
Alcoholis }

Dose for an adult, nine drops three times daily in half a teacupful of water containing a tablespoonful of brandy or two tablespoonfuls of wine. The nine drops of the mixture, containing three of the creasote, have been increased to twelve drops, or four of creasote, and, thus far in my practice, patients believe that they have been benefited by this remedy, and have desired to continue it. At the same time, in some instances, I have recommended the inhalation of ten or fifteen drops of the same mixture from Robinson's inhaler. This dose of creasote, three or four drops, may seem large, but it is tolerated when sufficiently diluted, though it may be best to commence with a smaller quantity. Children should, of course, take doses proportionate to the age, the fractional part of a drop being sufficient for infants. Creasote has also been injected into the tubercular lung through the chest-walls by several physicians, a syringe provided with a long and delicate needle being used. Rosenbusch injected eight drops of a three per cent. solution of creasote in almond oil in two places at the seat of the disease, or sixteen drops in all. The result was a marked diminution of the cough, the sweats, the amount of sputum, and, in recent cases, an increase in weight. The beech creasote was used, and the skin and apparatus were first sterilized by an antiseptic lotion. When the instrument was not introduced deeply enough, a sharp, pleuritic pain sometimes occurred, but it soon abated. Creasote appears to be the most valuable of the recent remedies recommended for tuberculosis, but in order to determine its exact value, the proper mode of employing it, and the size and frequency of the dose, more extended observations are required. Fräntzel says that experiments have shown that this substance is inimical to the growth of the bacillus when min-

[1] Medical Chronicle, July, 1887.

gled in minute quantity with a gelatin culture-medium, and on this fact is based its internal administration. When it is injected into the lungs through the chest-walls, Dr. E. G. Janeway, of New York, believes that it is very important that the almond oil or other vehicle employed should be first sterilized.

Iodoform.—This agent, dissolved in ether and inhaled, has been recommended. It apparently gives some relief to the cough, and possibly to other symptoms, but the belief that it is destructive to the bacillus has been shown to be fallacious by the experiments of Roosing, who inoculated the eye of a rabbit with tubercular matter mixed with iodoform, and the iodoform did not prevent or retard, but apparently accelerated the development of tubercle at the point of inoculation by its irritating effect upon the eye.[1] Iodoform cannot, therefore, be recommended as a curative agent in tuberculosis.

Biniodide of Mercury, Corrosive Sublimate.—Miguel and Rueff employed a solution of biniodide of mercury, 1 part to 40,000, as a germicide spray in tuberculosis. They state that of twenty-seven patients treated by this spray, nineteen improved, and the remaining eight were neither made better nor worse. It is unfortunate that the results of treatment by the biniodide, as observed by these physicians, were not stated more in detail. If they relied entirely on the opinions of the patients, they may have been deceived, for patients with chronic diseases often believe for a time that they are benefited by new modes of treatment, when there is no actual improvement.

The fact that corrosive sublimate employed internally and locally in the treatment of diphtheria has the confidence of the profession as an efficient germicide, suggests its use in the treatment of other microbic maladies. Moreover, its use in diphtheria has shown us what doses of this powerful agent can be safely prescribed. I am not aware that corrosive sublimate has been employed internally in the treatment of tubercular patients, but it has been used as a spray. In the Charity Hospital, several of the patients inhaled from the atomizer one teaspoonful of an aqueous solution of corrosive sublimate, two grains to the pint, every three to six hours, and both the patients and house-physicians believe that it acts beneficially in relieving symptoms, especially the cough. It cannot be doubted that the spray employed as often as every third hour disinfects the sputum to a great extent, and destroys the bacilli upon the surface of the larynx, bronchial tubes, and in the alveoli, but whether benefit may accrue to consumptives from its internal use we have not sufficient data for determining.

Another medicine which has been considerably employed in Europe, and in regard to which opposite opinions are expressed, is hydrofluoric acid. MM. Seiler and Garcin, of Paris, detailed the results of their use of this agent in a paper published in 1887 in the *Bulletin de l'Académie de Médecine.* They state that of 100 tubercular patients treated by hydrofluoric acid, 35 were cured, 41 exhibited more or less improvement in symptoms, 14 were not benefited, and 10 died. They state that in the favorable cases rapid improvement was observed in the symptoms, such as the fever, night-sweats, dyspnœa, and expectoration. Giacomi, of Berne, employed a mixture of 100 grammes of hydrofluoric acid with 300 grammes of water in a vessel over a spirit-lamp. Eight patients inhaled the vapor one hour each day. In one, marked relief occurred; in another some temporary improvement took place as regards the appetite and dyspnœa, but in the remaining six the result was negative. No discomfort resulted from the inhalation, though from the well-known action of hydrofluoric acid the window panes became more or less opaque. Gager has treated seventeen cases with the vapor of hydrofluoric acid with the following result: In five the bacilli disappeared from the sputum and the auscultatory signs improved in a marked degree; in seven some improvement in the physical signs occurred; in twelve the weight increased; in five cases no result.[1] Grancher and Chautard experimented with hydrofluoric acid on rabbits, and they express the opinion that the vapor of this agent does not penetrate sufficiently to destroy bacilli in the depth of the tissues. Trudeau states that the vapor of hydrofluoric acid is efficient as an antiseptic, and seems to possess greater penetrability than the ordinary antiseptic sprays, but it can only destroy those bacilli with which the inhaled vapor comes in contact; therefore, the bacilli imbedded in tubercular nodules and the tissues escape.[2] Professor Jaccoud inoculated guinea-pigs with tubercular sputum which had been subjected to the action of hydrofluoric acid, and produced tuberculosis with this sputum as certainly as with sputum not thus treated. From these experiments, and others performed under his direction, Jaccoud believes that the vapor of hydrofluoric acid, employed in any safe manner, does not destroy the tubercle bacillus or notably diminish its virulence.[3] Therefore, the good effects from the use of this medicine, claimed for it by those who first employed it, have not been realized in the practice of more recent observers, so that we cannot recommend its employment in the place of remedies which have produced more favorable results.

Rectal Injections of Sulphuretted Hydrogen.—This treatment was first employed by Dr. Bergeon, of

[1] London Lancet, January 21, 1888.

[2] THE MEDICAL NEWS, May 5, 1888.

[3] London Lancet, November 10, 1888.

Lyons, and being highly recommended by him, has been prescribed by many physicians in Europe and America. Its real value has now been apparently fully ascertained. The history of its use is instructive, since it shows how a mode of treatment which is inert may gain the confidence of intelligent physicians. The *British Medical Journal*, May 21, 1887, states that Dr. S. Cayhill, of the Isle of Wight, has employed Bergeon's treatment in private and hospital practice with the most encouraging results. He believes it is the greatest advance ever made in the therapeutics of pulmonary diseases. Dr. Henry Bennet also notices favorably Bergeon's treatment in the same journal for December, 1886. The late Dr. Bruen, of the University of Pennsylvania, treated 25 cases by Bergeon's method, employing twice daily from three quarts to a gallon of the gas slowly introduced. In nearly all the cases the night-sweats ceased, the cough, expectoration, and frequency of the pulse diminished, and the temperature fell half a degree to one degree.

On the other hand, Drs. Shattuck and Jackson, of Boston, employed Bergeon's treatment in 7 cases. No odor of the gas could be detected in the breath of these patients after its use, and paper moistened with a solution of the acetate of lead was not blackened when held before the mouth. The only result which might be attributed to the enemata was some diminution in the expectoration. Professor Austin Flint has made experiments in order to determine whether sulphuretted hydrogen introduced per rectum or by subcutaneous injection enters the lungs. He tested the expired air by holding before the mouth white filter paper moistened with a solution of acetate of lead. He ascertained that sulphuretted hydrogen was not exhaled at all, or was exhaled in small quantity, and for a period not exceeding three minutes. The presumption is, therefore, strong that sulphuretted hydrogen employed per rectum or subcutaneously, in some instances does not enter the lungs, and in other instances enters them in small quantity and is quickly expelled. Dr. Grauer placed cultures of the tubercle bacillus, as well as of other pathogenic germs in test-tubes, and subjected them to a current of sulphuretted hydrogen from two hours to a longer time, and yet their vitality was preserved, so that successful inoculations or cultures were produced. Dr. E. C. Trudeau, of Saranac Lake, says that in May, 1887, a tube containing a pure culture of the tubercle bacillus was subjected for thirty minutes to a stream of undiluted sulphuretted hydrogen made from sulphide of iron and sulphuric acid. The conducting tube was pushed through the cotton and held within half an inch of the coagulated serum, and the jet of gas allowed to play freely on the bacilli upon its surface. The entire mass soon became so blackened by the action of the sulphur as to resemble dark-gray paint. The microbes thus treated were then mixed with sterilized water and injected into the pleural cavities of two full-grown rabbits. These animals were then placed in a large box, well fed, and kept under a shed in the open air all summer. On October 19th, 162 days after the inoculation, both rabbits died within two hours of each other, and both were found to have cheesy bronchial glands and advanced pulmonary tuberculosis. The benefit, therefore, supposed by some to be derived from Bergeon's treatment, is probably due to hygienic measures.

Sulphurous Acid.—Dr. Dariex, in a monograph published in the *Bulletin Général de Thérapeutique*, February 29, 1888, states that Galen, in the second century, recommended the sulphurous air of volcanoes for consumptives. In recent times attention has been drawn to the beneficial effects of the inhalation of sulphurous vapors in tuberculosis by M. Salland, an army surgeon. A sergeant having this disease, which was progressing notwithstanding active medication, was placed in charge of the rooms in the barracks in which sulphur was burned for disinfecting purposes. This service obliged him to pass nine hours each day in a sulphurous atmosphere. At the end of sixty-five days he was cured. M. Auriol having observed the good effect of the inhalation of sulphurous acid upon certain consumptives, whose occupation compelled them to live in an atmosphere charged with this gas, fitted up a room for the treatment of this disease. The flowers of sulphur, slightly moistened with alcohol, was burnt in the corner of the room. Soon the patient began to have paroxysms of coughing, but he did not leave the room until moistened test-paper began to redden; if the respiration was much oppressed he left the room sooner or the window was opened. In order to render the vapor less irritating, and the paroxysms of coughing less severe, a little benzoin or powdered opium was added to the sulphur. These inhalations were practised morning and evening, the patient fasting, and afterward exercising in the open air. Appropriate medication, according to the symptoms, completed the treatment. Seventy patients, at different stages of tuberculosis, were subjected by M. Auriol to the inhalation of the sulphur vapor. Their sputa, previously examined, contained bacilli, and, inoculated in the guinea-pig, caused phthisis in a short time. Thirty of these patients, who were in incipient tuberculosis, obtained an arrest of the progress of the disease, disappearance of the fever and sweats, return of the appetite and increase in weight. The bacilli disappeared from the sputum. M. Auriol believes that these cases are cured, since the improvement has continued more than two years. The tubercles, he thinks, are transformed into fibrous tissue. Twenty others of the seventy tuber-

cular cases did not have this treatment long enough to determine its value, or received it in an irregular manner. Nevertheless, they stated that they derived benefit from it. The remaining 20 had general tuberculosis and succumbed to the disease. M. Auriol employed sulphurous acid in the treatment of guinea-pigs that were rendered tuberculous by inoculation. They improved in flesh and weight, and in those that were killed a considerable time afterward, the tubercular nodules were found to be transformed wholly or chiefly into fibrous tissue.

M. Dujardin-Beaumetz has constructed a very ingenious and simple lamp for producing sulphurous acid by burning the bisulphide of carbon. This produces 111.3 volumes of carbonic acid and 141.4 volumes of sulphurous acid. The carbonic acid does not seem to produce any injurious effect, but, on the other hand, its anæsthetic action increases the tolerance and diminishes the irritation of the sulphurous acid. The *Bulletin Général de Thérapeutique*, February 29, 1888, contains a full description of Dujardin-Beaumetz's apparatus, which is too lengthy for insertion here.

I have described in the foregoing pages the most important of the remedies which have been recently recommended by apparently competent observers. There are others, which, from their nature and the limited trial which they have received, I have not thought of sufficient importance to require notice. Most of them will probably soon be discarded by those who now recommend them. The hygienic measures—as outdoor life, residence at a high altitude, free ventilation of sleeping apartment, and the use of the most nutritious and easily digested food—still maintain a most important place in the treatment of tuberculosis. Of the medicines, creasote used internally and by inhalation, the inhalation of sulphurous acid vapor, not carried to the extent of irritating the air-passages, and the use of germicide sprays, as of corrosive sublimate, the terebinthinate vapors, etc., appear to be the most deserving of recommendation. But no doubt the next ten years will witness important changes in the treatment of tuberculosis, based on its microbic nature, and probably remedies not now heard of will come into use.

A CASE OF ECTOPIC GESTATION WITHOUT CHARACTERISTIC SYMPTOMS.

By J. M. BALDY, M.D.,
of Philadelphia.

The following case is reported because it well illustrates some points in the much disputed question of the diagnosis of early ectopic gestation :

F. C., age twenty-four years; white; married for nine years. Has had two children and no miscarriage. The last pregnancy was six or seven years ago. After this labor she was in bed for eight weeks with a "sore and swollen belly," and since then she has never been free from pelvic and abdominal pain. Her menstruation has been regular but very profuse, lasting eight or nine days. In the interim between her first illness (following the birth of her child) and the present, she had an attack of abdominal pain, which confined her to bed for a week or more.

On November 15, 1889, she came to me stating that her regular menstruation had come on five weeks previously, and that she had been bleeding more or less ever since; the constant pain she had been having had become worse. She had the appearance of a very sick woman, her temperature was elevated, her pulse quick, and she was having chills and "creeps." An examination of the pelvis showed the uterus in fair position and of normal size. There were irregular cystic masses on each side, the largest being on the right. The necessary manipulation gave her much pain. A diagnosis of chronic double pyosalpinx, with an acute attack of pelvic peritonitis, was made, and an operation for the removal of the tubes was advised. She was admitted to the woman's ward of the Howard Hospital, and an operation made on November 21st. From the right side a tubal pregnancy was removed, which had advanced to about the sixth or seventh week; from the left side an ovarian cyst the size of a hen's egg.

The results of the operation were a complete surprise to me. My diagnosis of pyosalpinx—which was concurred in by my friend Dr. Bradford—was made with the utmost confidence, and we had not the slight estdoubt that it would prove to be such. An ectopic gestation never entered into consideration. As soon as the patient was well enough I questioned her closely to see wherein I was at fault in my conclusions. A most careful questioning of her disclosed the following facts :

At no time during the past year had she missed a menstrual period, nor had there been a scant or delayed one. At no time had she had any signs of pregnancy, such as she suffered from when she was previously impregnated. In fact, she does not even now believe that she was pregnant, basing this scepticism on the absence of a missed period and the early signs of pregnancy. Her breasts were of the normal size, the areolæ were not enlarged or changed in color, there was no tingling or itching about the breast, though they contained a small quantity of milk. However, she states that such had been their condition since the birth of her last child. There was no decidual discharge. The only thing she passed besides blood was a piece of whitish matter, such as she was in the habit of passing at the end of each menstrual period. This point has been most carefully inquired into, and she answers very intelligently. In addition to her statements, we have those of a careful trained nurse. The patient was in the hospital for two or three days before the operation, bleeding constantly. The nurse declares that the napkins were soiled with a discharge entirely free from clots or shreds. Stomach symptoms were entirely wanting. The

pains were, according to her statement, not different from those she had with her previous attack of probable pelvic peritonitis.[1]

In the local examination there had not been noted any discoloration of the vagina, and the uterus was found to be of normal size. At the time of the operation, before I had discovered that I was dealing with an ectopic gestation, as I played my fingers around the uterus, I remarked that it was of natural size. The sensation conveyed to my finger, while palpating the lateral cystic masses through the vagina, was most remarkably like what I have felt in some pyosalpinx cases. In addition to all this, there were an elevated temperature, flashes of heat, and chilly sensations, all pointing to pus.

What symptoms, then, had we of extra-uterine pregnancy? Bleeding for five weeks, and pain, together with a period of six or seven years' sterility. All the other symptoms described as common to this disease were absent. The question arises, Could the correct diagnosis have been made on these data? I think not. The bleeding could easily be accounted for by the pelvic disease and the peritonitis which existed; and, as a matter of fact, she was in the habit of bleeding profusely at every period, and on a previous occasion, when she had a probable pelvic peritonitis, she bled irregularly for some weeks. The pain I believe to be the most valuable sign of ectopic gestation, it being, as a rule, of a character almost peculiar to itself. Here, however, I was not given the opportunity to see her in a typical spasm, and her own statement is that they differed from her old ones merely in degree, and in assuming, at times, a more cramp-like character. This, however, I only obtained from her after the operation, her statement before operation being that there was no difference. The combination of pain, sterility, and irregular, profuse bleeding is so common in pelvic inflammatory troubles that nothing unusual could be suspected from them alone. On the other hand, the previous history, the pelvic examination, especially the double nature of the affection, the elevated temperature, the chills, the evident chronic nature of the trouble with the acute attack of pelvic peritonitis supervening, all pointed almost conclusively to pyosalpinx. One more point might be added—she had lost flesh quite rapidly in the past five weeks.

To be doubly sure that the right tube contained an impregnated ovum, I took the specimen to Dr. George A. Piersol, of the University of Pennsylvania. After a microscopical examination which displayed the chorion villi most beautifully, he pronounced it an undoubted specimen of extra-uterine pregnancy.

[1] The patient was seen within the past ten days. The incision and tube tract are entirely closed. She has no pain, is quite fat, has a splendid appetite, and sleeps well. She occasionally spits a little blood.

Her recovery was complicated about the third day by a pneumonia (whether from the ether, from unavoidable exposure, from both or from neither, I am unable to say), and later by the drainage track becoming infected. Her convalescence was slow and incomplete. She left the hospital with the pulmonary trouble still hanging on. Later, she appeared at the out-patient department spitting bloody mucus. She was induced to enter the Pennsylvania Hospital, but became discontented and would not stay.

The points to which I would particularly call attention are:

First. That this was an unruptured or primary tubal pregnancy. (This is the second one of the kind I have had.)

Second. That there was no missed or scanty menstrual period.

Third. That there was no decidual discharge.

Fourth. That there were no breast or stomach symptoms, or other signs of pregnancy.

Fifth. That the woman did not think she was pregnant.

Sixth. That the uterus was of normal size.

Seventh. That the character of the pain was not markedly distinctive.

Eighth. That there was a tubal pregnancy on one side and an ovarian cyst on the other.

The case is one more illustration of the impossibility of an accurate diagnosis in ectopic gestation, and of how such a condition can exist without showing enough symptoms to cause even a suspicion of its existence.

328 SOUTH SEVENTEENTH STREET.

REMARKS UPON EMPYEMA.[1]

BY MARY PUTNAM JACOBI, M.D.,
OF NEW YORK.

(Concluded from page 122.)

THE use of a valve in the dressing of the empyemic fistula has received much less attention than it deserves. The elaborate valvular apparatus described by Phelps, in 1880,[2] does not seem to have been employed by any one else. It necessitates a double opening in the chest, and is otherwise too complicated for general use. When a valve of *bandruche* was used around the trocar, in the French method of operating which preceded the antiseptic, no arrangement was made for keeping up a valve action by the dressings. Dr. Cabot, in his paper of 1880, is the first writer I know of who has perceived the desirability of a valve. He recommends, however, to utilize the mackintosh of the Lister dressing for this purpose, allowing it to over-

[1] Read before the New York Academy of Medicine, Section on Pædiatrics, November, 1889.

[2] New York Med. Record, 1880.

lap the gauze upon the skin, instead of, as is usual, falling short of the dimensions of the gauze. It seemed to me that this same idea could be more effectively carried out by placing a piece of rubber tissue, the size of my palm, directly over the opening, upon the skin and under the dressing. The piece of rubber was, of course, previously soaked in a bichloride solution. After the conclusion of my case, I found that Bouveret has advised a similar valve to be placed directly over the fistula, but this to be attached to the upper border by collodion, and left free below. My thin layer of rubber tissue, as soon as it was *in situ*, became closely applied to the skin by atmospheric pressure.

On the first dressing a valve had been imperfectly applied, and continued to be so until the eleventh day. Up to this time air was always drawn into the lung as soon as the dressing was removed. On the eleventh day a better valve was made of thin rubber tissue, and a week later, when the discharge had almost entirely ceased, no air was drawn into the chest when the valve and dressings were removed.

It might at first sight appear as if a piece of rubber, closely applied over the opening as above described, would interfere with the discharge of pus through the drain. The discharge is, however, effected during expiration, when the intra-pleural pressure becomes superior to the pressure of the external air against the valve, and, therefore, raises it sufficiently for fluids to trickle out.

Peyrot[1] has shown that in pleural effusions the type of expiration changes; the force of inspiration diminishes as the expansion of the chest becomes incapable of determining a vacuum, and expiration becomes the principal act. It becomes active instead of passive, as is normal, and may be decomposed into two periods. In the first the glottis remains closed, and air is pushed toward the depths of the bronchi. In the second period the glottis opens, and air is expelled with a sigh. This form of respiration is normal to birds. It also greatly resembles that of frogs, where the lungs are not contained in closed cavities, and where, therefore, there is no mechanism for aspiring air by the creation of a potential vacuum. While the glottis is open air enters the upper air-passages. The glottis is then closed, and air is jerked toward the termini of the bronchi by movements resembling those of deglutition.

This change of respiratory type is well shown on some respiratory tracings taken from the right side of a dog's chest during successive injections of plaster-of-Paris into the left pleural cavity. The expiration begins to be prolonged and divided into two phases during the third injection, and from that moment the inspiration continues to diminish in amplitude and duration—the expiration to increase in both.

In another dog, where a carotid tracing was taken during the injection, the trace immediately showed an increase in the respiratory oscillations, and a rise of blood-pressure to the extent of five millimetres of mercury. After the fifth injection there was a second rise of blood-pressure to the extent of ten millimetres. When twelve ounces of plaster-of-Paris had been injected, the pulsations were arrested, and the manometer needle fell fifteen millimetres.

The change of respiratory type in pleural effusions is not due to pressure exerted on the lungs, but to the inadequacy of the inspiratory expansion to effect its purpose of drawing air into the lung. This inadequacy persists after evacuation of the fluid and establishment of a fistula, although the abnormal positive intra-pleural tension be then greatly diminished. Therefore, the new type of breathing persists, though to a less degree. It would be very interesting to demonstrate this upon the human subject, but I have not been able to do so.

It is easy to see that the change of type is an advantage in the double task imposed—that of expelling fluids from the chest, which must be effected during expiration, and of reducing to a minimum the aspiration of air into the pleura, which would be effected during a vigorous inspiration. Correlatively with these desiderata, which inverts the normal ones, we find experimentally, and shall probably find clinically when we look for it, that the normal force of the respiratory movements is inverted—inspiration is diminished and expiration is increased.

The immobilization of the chest walls on the affected side while an intra-pleural effusion exists, and their collapse—especially marked in children after the fluid is evacuated—seem to be the mechanism by which inspiration is diminished. The cough, which, as in our case, comes on or is aggravated after the operation, is one of the means by which expulsive expirations are increased.

With these favoring circumstances, even the ordinary Lister dressing often suffices to solve the problem of so greatly diminishing the entrance of air through the fistula, that the air remaining within the pleura may become rarefied, the lung submitted to unopposed atmospheric pressure, and, therefore, reëxpanded. This is the true mechanism of the clinical phenomenon which Dr. O'Dwyer has recently discussed with a certain despair of finding the explanation. Although air be not absolutely excluded from the pleura, yet if it be not renewed, or renewed in less proportion than it is absorbed, it will soon become rarefied, and the conditions of pulmonary reëxpansion are then established as posi-

[1] Archives Gén. de Médecine, 1876.

tively, though less vigorously, than when a complete vacuum exists.

Homolle[1] has contrived to measure intra-pleural tensions by means of a manometer attached by a lateral stop-cock to the trocar used in evacuating effusions. In a case of empyema the measurements varied thus:

Before any fluid was withdrawn the intra-pleural pressure was positive, and equivalent to ten millimetres of mercury. When 500 grammes had been withdrawn, it had sunk to 0.002 millimetre; when 900 grammes, the pressure became negative to the extent of 0.007 millimetre, and after withdrawing 1000 grammes, the negaive pressure was eighteen millimetres.

In the dog in whose pleura I injected water through an air-tight canula communicating with a manometer, the pressure was negative to the amount of five millimetres, and remained so after 300 grammes of water had been injected.

These facts show that the pleural cavity may contain some air and some fluid, and yet remain in a state of negative pressure relative to the atmospheric air, which, therefore, should not be opposed in expanding the lung.

As Weissberger has further pointed out, during the process of adhesion and obliteration of the pleural cavity the lung becomes tugged forward piece by piece, and when the adhesions are complete, the lung must be drawn out by every expansion of the thorax.

The presence of fluid in the chest when there is a free opening for it to run out, offers little more obstacle to the reëxpansion of the lung than does the pressure of fluid in the flask to the reëxpansion of the balloon. This is because the pressure of the fluid is always superior to that of the external air, and therefore easily overcomes it.

It is the clinical observation of frequent and even speedy recovery with the use of the Lister dressing alone,[2] which demonstrated that the above processes must take place as described.

But whatever beneficial influence, from the dynamic point of view, may be exercised by the Lister dressing, is certainly greatly intensified by the use of such a valve as I have described. I think there is no doubt that the cavity became contracted to a sinus on the fifteenth day after the operation, and that the tube might have been removed at least ten days earlier than it was.

To the extent to which the occlusion of the fistula during inspirations is complete, the normal type of respiration tends to be reproduced, and the cavity to be obliterated by more vigorous inspiration of the lung.

Peyrot remarks that when, being bound by false membranes, the lung is unable to expand, the diminution of pressure in the pleura seems to favor putrefaction or fermentation, even without contact with external air. The importance of the pulmonary expansion as a means of obliterating the cavity is so great, and as such has always been so well recognized, that the frequent failures of such methods as subaqueous drainage[1] seem more surprising than its successes. These failures are the best possible proof that the antiseptic part of the problem is as important as the mechanical; that sepsis is liable to occur through infection of the external wound, even when air is rigorously excluded from the pleura; and finally, that constant irrigation of granulation tissue that should be left in the greatest repose, interferes both with the healing and with the mechanical mechanisms of reëxpansion. During the treatment of the boy Frank, I took a certain number of casts of his chest, by a process which is very simple, but which I have not hitherto seen described. I encircled the thorax with a cytometer, and having carefully removed the instrument I placed it, closed, on a perfectly flat surface, and poured in fluid plaster-of-Paris. A cast was thus obtained, one-half an inch in thickness, and which accurately represented a transverse segment of the chest, and the inequalities of the two sides. The

CAST I.

first cast was taken on the eighteenth day, a week after the irrigation. It represents a segment imme-

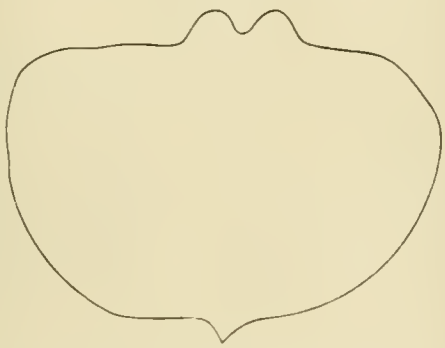
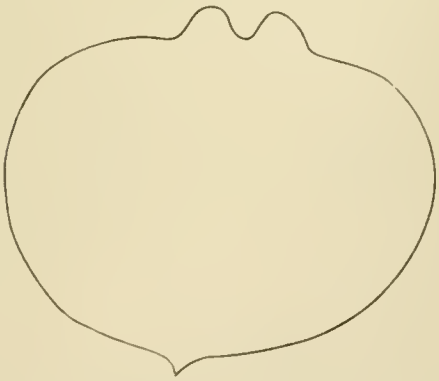
a few days after cicatrization. No. III. from the level of the axillæ, No. IV. from the level of the seventh rib. The odd-looking projections on the

CAST III.

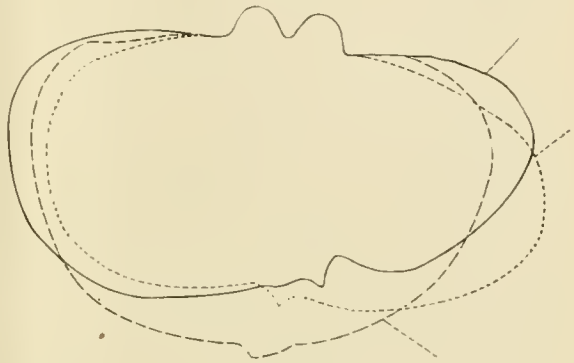


posterior aspects of these casts are due to a mistake made in the application of the cytometer, which was put on inside out. This does not, however, essentially change the character of the casts.

CAST IV.



The general shape of the affected side in the fourth cast well illustrates Peyrot's remark, that there is a total deformity of the chest, which results in a sort of "oblique oval thorax." I regret very much not to have secured a cast on the preceding week, as then the affected side was much more collapsed, the shoulder drawn over and downward, so that the alarmed parents inquired about the danger of permanent deformity. The cast of the eighteenth day shows: First, a deviation of the sternum toward the affected side, and half an inch to the left of an antero-posterior line traversing the segment from the vertebral column. Second, a marked diminution in circumference, in transverse and in antero-posterior diameters as compared with the sound side.[1] The cast taken the following week, however, shows that the differentiation on the first occasion had depended upon an enlargement of the right half of the chest, as well as on the contraction of the left. The deviation of the sternum was



Casts superimposed.

much less; and the right circumference both to the deviation and to the median line was two inches less than it had been before the transverse diameter was diminished an inch; the antero-posterior the least of all—a quarter of an inch.[2] The measurements of the left side are increased, not only over those of the previous week, but over those of the right side, except the antero-posterior diameter, which is still one-quarter inch smaller. As before, the transverse diameter exceeds the antero-posterior.

In the following week, after cicatrization of the fistula, the sternum has returned to the median line,

[1] Measurements, October 14th:

	Inches.
Circumference, left (affected side), to point of deviation of sternum	7½
Circumference, right, to point of deviation of sternum	10½
Circumference to median line, left	8¼
Circumference to median line, right	10
Transverse diameter to median line, left	3¼
Transverse diameter to median line, right	4¼
Antero-posterior diameter, left	3
Antero-posterior diameter, right	4

Transverse diameter, left	4¼
Transverse diameter, right	3¼
Antero-posterior diameter, left	3½
Antero-posterior diameter, right	3¼

the diameters of the two sides of the chest are nearly the same, but the right circumference exceeds the left by one and a half inches. Below, at the level of the xiphoid cartilage, the circumferences are equal; to the median line, both diameters larger on the right side by one-quarter inch.[1]

It is interesting to be able to measure thus graphically the compensatory hypertrophy and shifting of the sternum and mediastinum during the collapse of the left lung, and the gradual diminution of this hypertrophy and restoration of normal proportions as the collapsed lung expanded.

In concluding this paper, which has not aimed at being systematic, but which has taken up details of interest as they occurred to me, there is one further remark to make. It seems to me that the two common observations of the frequency of empyema in children, and of its usually favorable course, are observations mutually correlative. The favorable prognosis does not apply to the empyemas of infectious diseases; nor is it solely due to the greater elasticity of the chest walls in childhood, permitting more facile collapse. But the appearance of pus in the effusion is to be considered less significant, because more easily excited by the same degree of inflammation. It would seem as if the rich system of subendothelial lymphatics in the pleura,[2] poured out leucocytes freely through the intercellular stomata, when these are dilated in the inflammatory hyperæmia of the pleura, and during the preliminary shrinkage of the endothelial cells.[3] Pus, therefore, appears in the effusion before the pleura has became thoroughly infiltrated, and continues to be secreted so long as the stasis remains in the vascular and lymphatic capillaries.

The Flushing Hospital.—The hospital at Flushing, Long Island, has recently received a bequest of $10,000 under the will of the late John Henderson, the well-known seedsman.

A CASE OF DIFFUSE SUPPURATIVE PERITONITIS FOLLOWING PERFORATION OF THE APPENDIX VERMIFORMIS.[1]

BY JOHN R. WINSLOW, B.A., M.D.,
PROFESSOR OF PHYSIOLOGY IN THE WOMAN'S MEDICAL COLLEGE OF BALTIMORE

AT 3.30 A.M., Wednesday, November 20th, I was summoned to see Willie S., aged nearly seventeen years, and was given the following history: After returning, apparently in perfect health, from his usual daily work, the boy had eaten very heartily of buckwheat cakes at supper. About three o'clock in the morning he was seized with violent cramps, but was for some time unable to arouse any of the family, so that he had been suffering nearly an hour before my arrival. When I first saw him he was suffering from intermittent pains, not very frequent or severe, and was vomiting freely. He had slight fever (temperature 100⅖°, pulse 120).

Believing it to be an ordinary case of cholera morbus, I administered 1/6 grain of sulphate of morphine hypodermically, and directed the mother to give a dose of oil in the morning.

About the middle of the day I received word that the boy was still suffering somewhat, although better, and I was requested to call again. Upon my arrival I found the patient lying flat on his back in bed, complaining of some soreness in the lower portion of his abdomen, but particularly of nausea. He had no fever and a fairly good pulse. Upon inquiry I found that the oil had been given but with no effect. I palpated the abdomen superficially without eliciting any complaint or sign of pain. In view of the failure of the castor oil to open the bowels, I ordered half an ounce of magnesium sulphate, to be repeated within two hours if necessary.

Next morning (Thursday) I found that both doses of Epsom salts had been given without effect. Patient, however, felt better: temperature 97°; pulse fair; occasional vomiting. I then examined the abdomen with the greatest care for any induration or tenderness, and found nothing noticeable in these respects. During the examination, however, I noticed that the fibres of the abdominal muscles were somewhat more perceptible than usual, but would not describe the sensation as that of "board-like hardness." I inquired particularly as to the character of the vomited matter, and found that it presented neither the odor nor the appearance of fæces. In the evening I found much the same condition of affairs; temperature subnormal, pulse, however, very rapid—150. The bowels had not been moved. I then ordered a mixture, essentially a compound infusion of gentian, to be given by the mouth, and if vomited to be repeated *per rectum*.

Next morning (Friday) I found that the dose by the mouth had been vomited, but the enema had caused a slight movement of the bowels. Patient seemed better, pulse slower and fuller, temperature still subnormal. In view of the apparent improvement, I ordered the enema to be repeated. This caused, during the afternoon, several good though not copious evacuations of that greenish character

[1] Read before the Clinical Society of Maryland, Dec. 20, 1889.

popularly ascribed to bile. An improvement in the patient's condition resulted.

Being, however, uneasy about him, I called early next morning (Saturday) to see him. I found him without radial pulse, and cold, but perfectly intelligent and complaining of feeling weak. I resorted to most vigorous stimulation, and in the course of an hour after the injection of whiskey and nitroglycerin hypodermically, I succeeded in developing a radial pulse. I then ordered tincture of digitalis ten drops, and left to secure the opinion of my brother, Dr. Randolph Winslow, as to the advisability of a laparotomy. Upon our return, within half an hour, we found the patient again without radial pulse, and laparotomy was, of course, out of the question. He became weaker and weaker, notwithstanding vigorous stimulation, and died just before 12 M. of the same day.

At my first visit in the morning, upon finding my patient in a condition of collapse, I had expressed the opinion to the mother that he had a "hole in his bowels," and after death I requested an autopsy. The request was, as is usual, refused, but was subsequently granted, owing to the persuasive eloquence of the colored undertaker, coupled with the remark that "they would do it anyhow at the health office."

Autopsy.—Upon the day succeeding death my brother and myself performed the post-mortem, and found the following conditions: The abdomen was considerably swollen and more discolored than is usual so soon after death. Upon making an incision through the peritoneum pus escaped through the opening in considerable amount; the intestines were somewhat adherent to the abdominal walls, but not to a marked extent. Upon exposing the abdominal contents a condition of intense purulent inflammation was revealed. The intestines were bathed in malodorous pus and covered in places by deposits of lymph. Pus was everywhere, even under the liver, and could only be drained off by cross-cutting the abdominal wall and turning the cadaver on its side.

After draining off about a quart of pus, we proceeded to examine systematically the intestinal tract; the upper portion seemed to be of normal color and appearance; the pelvic coils, however, were dark and enlarged. The focus of inflammation was in the right iliac fossa, which contained a considerable quantity of liquid fæces. The cæcum and adjacent portions of the colon and ileum were firmly bound down.

The vermiform appendix was intensely inflamed, and was adherent to the cæcum; it was much distended, especially near its middle, where a hard lump could be both seen and felt; just below this was a perforation of considerable size, with gangrenous edges; the lumen of the appendix was found to be largely filled with hardened fæces, which formed a cast of its interior.

Post-mortem Diagnosis.—General suppurative peritonitis. *Acute,* for there was no evidence or history of previous attack. "Fulminating," for its entire duration was less than four days.

In conclusion, allow me to emphasize the following points presented by this case:

1. Subnormal temperature (oral). With the exception of the incipiency of the attack, during the entire course of the disease the temperature was subnormal, varying from 95° to 97°, being at no time below the former or above the latter temperature.

2. The absence of abdominal tenderness. At no time was there marked tenderness of the abdomen. I sought carefully for it, and upon the morning of death my brother also palpated the abdomen without causing any expression of pain from the boy. He complained simply of soreness in the lower portion of the abdomen, which was diffuse and not confined to one side. Nor was this soreness marked enough to require the administration of opiates.

3. Obstinate constipation.

In the light of the post-mortem examination we may thus explain the course and symptoms of the case; the trouble originated with the impaction of fæces in the vermiform appendix; this occurred before, and was not connected with, the ingestion of the large meal of buckwheat-cakes. The colicky pains and fever marked the perforation of the appendix at a point weakened by ulceration. This permitted the escape of liquid fæces into the abdominal cavity, setting up at first localized and then general purulent peritonitis.

The obstinate constipation was due to paralysis of the intestinal walls, from the peritoneal inflammation.

Since the difficulty with these cases lies in the diagnosis, and since it is, as a rule, the general practitioner who must detect them, a few practical points in connection with the same may not be out of place.

Persistently subnormal (oral and axillary) temperature and absence of abdominal tenderness, present in this case, together with a "board-like" hardness of the abdominal walls, which was not present, are, if not pathognomonic, at least frequently associated with suppurative peritonitis.

One precaution,[1] however, in regard to the temperature is necessary. To appease the intense thirst of this condition, *ice and cooling drinks* are resorted to, which renders the taking of temperature *per os* fallacious.

The rectum, being in close proximity to the peritoneum, affords an almost direct means of obtaining the true temperature of the peritoneal cavity. In cases of inflammation, the rectal temperature is never subnormal. There may be a difference of several degrees between the axillary and the rectal temperatures, and the former may be subnormal, while the latter indicates high fever.

[1] A most valuable point raised by Dr. L. McLane Tiffany in discussing this case

TREPHINING FOR EXTRA-DURAL HÆMORRHAGE.

BY JOHN B. DEAVER, M.D.,
DEMONSTRATOR OF ANATOMY AND LECTURER UPON SURGICAL ANATOMY IN THE UNIVERSITY OF PENNSYLVANIA; ATTENDING SURGEON TO THE GERMAN, PHILADELPHIA, ST MARY'S, AND ST. AGNES'S HOSPITALS, PHILADELPHIA, PA.

APPARENTLY, much has been done in the past two years in brain surgery, and by far the greatest number of operations and reported successes have been for focal or Jacksonian epilepsy. In this class of cases the immediate results have been good, but we cannot say this of the remote; and, therefore, in my judgment, I consider that beyond giving temporary relief, or beyond holding the trouble in abeyance for a time, these operations have accomplished most in demonstrating the amount of manipulation the brain is capable of permitting, providing that this is done by skilled hands, and that every possible antiseptic precaution is taken. Again, the lateral ventricles have been tapped, but this offers no more than temporary relief. It does not by any means remove the factor, which is slowly but surely killing the patient. This is true to a great extent in the case of tumors, as we know that the most common brain tumors are tubercular, sarcomatous, and syphilitic, and therefore in the event of their successful removal the patient is not restored to a normal condition, but is left crippled. The more favorable results have been obtained in tumors springing from the dura mater or membranes, and which are not strictly tumors of the brain substance but invade it by pressure, excavating for themselves a bed or nest.

Contrast with the above trephining for intra-cranial hæmorrhage, particularly of the extra-dural variety; here the operation, if done early, is in every sense a life-saving agent, practical as well as permanent in its results in the majority of cases.

Of the varieties of intra-cranial hæmorrhage we have four:

1. Where the blood escapes or finds its way between the inner wall of the cranium and the dura mater.

2. Where it finds its way into the sub-dural space.

3. Where it finds its way into the sub-arachnoid space and into the meshes of the pia mater.

4. Where it escapes into the substance of the brain or into the ventricles.

Erichsen gives the third variety as the most common form of intra-cranial hæmorrhage, while Prescott Hewitt gives the second; but in the cases which I here report, and in which I trephined, all were of the extra-dural variety.

When blood is poured out between the dura mater and the bone, in cases of fracture, the vessel that is torn, as a rule, is the middle meningeal artery. Mr. Jacobson has shown that the branches of this artery are more frequently ruptured than the trunk. The vessel is very frequently torn at the point where it crosses the anterior inferior angle of the parietal bone. The reasons for this are: 1. That the bone at the site of the groove for the artery is very thin. 2. That the vessel is so frequently buried in the bone that fracture without laceration of the vessel is hardly possible. 3. That this part of the skull is peculiarly liable to be broken. It has been shown that the artery may be ruptured by force sufficient to occasion detachment of the dura mater, but not great enough to fracture the skull. Next to the middle meningeal, the most frequent source of extra-dural hæmorrhage is the lateral sinus.

On referring to the attachment of the dura mater to the interior of the cranium, we find that it is very intimately adherent to the bone forming the interior of the wall of the skull; therefore this variety of hæmorrhage in this situation is barely possible. Over the vault of the cranium its attachments are comparatively loose, except along the lines of the sutures. Bell has pointed out that the dura mater of the vault may be separated from the bone by the vibration produced by a blow. Strike the skull of the subject with a heavy mallet, and on dissecting you find the dura mater shaken from the skull at the point struck. Repeat the experiment on another subject, and inject the head minutely with injection fluid, and you will find a clot of injection lying between the skull and the dura mater at the part struck, and having an exact resemblance to the coagulum found after a violent blow on the head. Tillaux has demonstrated that the adhesions between the dura mater and the bone are particularly weak in the temporal fossa, the most usual site of meningeal hæmorrhage.

In the diagnosis of extra-dural hæmorrhage the following points are to be observed:

The *mental condition* may be normal, or there may be cerebral irritation. Unconsciousness, complete or incomplete, or coma.

Condition of Pupils.—Both may respond to light normally. Both may be dilated, and show no response; or one may be widely dilated, and the other normal. When the dilated pupil corresponds to the injured side, it is caused, as pointed out by Hutchinson, by the pressure of a large clot, extending deeply down into the base of the skull, on the cavernous sinus, leading to fulness of the vessels, with protrusion of the eyeball and dilatation of the pupil. It is also accounted for by compression of the oculo-motor nerve, through the medium of the clot.

Respiration may be stertorous, or Cheyne-Stokes in character.

Pulse.—Little changed or rapid and feeble, depending largely on the severity of the concussion,

or slow and full depending upon the severity of the compression.

Limbs.—May present any of the following conditions: Hemiplegia, well or but little marked; monoplegia, paralysis, twitching, convulsions, or spastic rigidity.

Scalp.—Presence of contusion, or bagginess due to the injury; the latter also due to leakage from within the cranium through a fissured fracture.

The stages presented by a typical case of extra-dural hæmorrhage are three:

1st. Complete or partial unconsciouness, the result of the concussion or shock, caused by the fall or blow, as the case may be.

2d. Consciousness or lucidity. This stage may vary in length from a few minutes to several hours. "Is present in about one-half of the cases," says Jacobson.

I have observed that a very large hæmorrhage may produce compression at once; my observations being verified by post-mortem examination. Compression may also come on immediately, caused by coexisting depression of bone, injury to the brain, and alcoholism.

The following case, which is a good example of all three, is of interest:

H. K., twenty-three years old, white, was admitted to the German Hospital, December 19, 1889, 12.30 P.M., having met with an accident, the history of which is as follows: He had fallen a distance of fifteen feet through an elevator, landing on the top of his head. His condition, as described by the resident physician, Dr. Gerlach, upon admission, was: Complete unconsciousness; pupils responding to light; conjunctival reflexes active; respiration 24; pulse 100; temperature 99°. The scalp was much swollen and boggy over the whole of the left side and vertex, with a lacerated wound of the right ear at the junction of the concha with the scalp. Urine drawn, quantity small, normal in reaction and color; chemical tests for albumin and sugar negative. The patient remained in the above condition twenty minutes, when he regained partial consciousness for about five minutes; he was then seized with a general epileptiform convulsion, lasting one minute. The convulsion, as described by the Sister, was thought to have commenced in the right leg, but it became general so soon that she could not be certain. After the convulsion the patient could not be aroused fully, but showed some evidence of consciousness when spoken to. His breathing was embarrassed, the pulse full and strong. After an interval of ten minutes he was seized with another convulsion, lasting about double the length of the first, which was described by a second Sister present, as corresponding with that of the first seizure, but she too was in doubt about the spasm commencing in the right leg, as it became general so soon. Dr. Gerlach was sent for, but arrived too late to witness the convulsive seizures. The patient was now intensely cyanosed, respirations slow, deep, and stertorous, pulse slow and full. Upon my arrival at the hospital, but a moment or two later, very fortunately, I found his condition as above noted. Examination of the right side demonstrated the limbs to be slightly spastic, the left paretic. As there was but little doubt in my mind that the condition was one of intra-cranial hæmorrhage, and most probably of the extra-dural variety, there having been an interval of consciousness between the reaction from the concussion or shock, and the development of convulsions, I immediately prepared to trephine over the anterior branch of the middle meningeal artery. The scalp was quickly prepared for a strictly antiseptic operation, and ether administered. A large horseshoe flap, including all the layers of the scalp, with its convexity directed downward and backward, was turned up on the left side by carrying an incision from directly behind the external angular process of the frontal bone, to above and behind the parietal eminence; a fissured fracture was now seen following the coronal suture. To trace it throughout its entire length, two further incisions were made, one following the line of the coronal suture, the other from the termination of the latter, a short distance over the right parietal bone; when these flaps were reflected forward and backward, almost the entire vertex was laid bare. In the sub-aponeurotic space and infiltrating the areolar tissue of the scalp was an extensive extravasation of blood. The fracture extended from the beginning of the coronal suture to about one and a half inches beyond the sagittal suture; from this point a fissure extended obliquely downward and backward into the right parietal bone, also one obliquely forward and to the left, involving both the right and left frontal bones, stopping short of the supra-orbital margin. There was some bleeding from beneath the bone through the line of separation of the coronal suture, most marked on the left side. With a medium-sized trephine, an inch and a half in diameter, a button of bone was removed at a point one inch and a half behind the external angular process of the frontal bone, and one and three-quarters inches above the zygoma, when the anterior branch of the middle meningeal artery was exposed, the ends of which were ligated with catgut. The bleeding not being entirely arrested, with a pair of Hopkins's modification of the Rongeur forceps, the opening was enlarged in the direction of the groove in the squamous portion of the temporal bone, through which passes the posterior branch of the above vessel, when it was plainly to be seen that the source of the remaining hæmorrhage was most probably this branch near its point of origin; the opening was, therefore, enlarged in the direction of the spinous foramen of the sphenoid bone, and after cutting away bone to the extent of about one-half inch, the vessel was seen to be torn and bleeding freely. Both ends were tied with catgut, after which the hæmorrhage ceased. The cavity occasioned by the separation of the dura mater was washed out with a 1 to 2000 bichloride solution. I removed a second button of bone, three-quarters of an inch in diameter, from a point about three-quarters of an inch to the left of the sagittal suture, and about one

inch posterior to the separated coronal suture. This corresponded to the upper and posterior margin of the cavity caused by the separation of the dura mater. My object in doing this was to enable me to pass catgut drainage through this opening and out of the one first made, thus securing a perfect outlet to any liquid that would otherwise have a tendency to collect in the cavity. Through this last opening I incised the dura mater and exposed the sub-dural space, to determine whether or not there was either the second or third variety of intracranial hæmorrhage associated with the extra-dural which I had already checked. This proved negative. The incision of the dura mater was closed with catgut suture. The end of a rubber drainage-tube, one-quarter of an inch in diameter, was placed in the lower and anterior of the two openings made in the wall of the skull, and brought out at the lower angle of the scalp wound, where it was fixed by a silver wire suture, loosely twisted. A second rubber drainage-tube, the same size as the above, was placed beneath the scalp flaps, above the two trephine openings and brought out in front and behind, where it was fixed by silver wire suture. The flaps were now completely adjusted and held in apposition by interrupted silver wire sutures. Through the tubes a 1 to 2000 solution of bichloride of mercury was passed, and the wound dressed antiseptically. A hypodermic injection of one-eighth of a grain of morphine was given to the patient, when he was removed from the operating table. Dry heat was applied to the body and an ice bag to the head. He reacted nicely and slept for four hours after the operation, when he awoke and was fairly rational. Being now able to swallow, he was ordered milk diet and given one-quarter of a grain of calomel, with two grains of Dover's powder every two hours. At 8 P. M., six and one-half hours after the operation, he was perfectly quiet and entirely rational. Pulse 90; respiration 28; and temperature 100°. Pupillary reaction normal; he was able to execute the ordinary movements with his extremities, and said that he felt pretty comfortable, although he had some pain in his head during the night and was somewhat restless.

December 20. Condition unchanged from that of the previous evening.

At 3.30 A.M., December 21st, had a slight convulsion, beginning in the right upper extremity with flexion of the hand upon the wrist, then the forearm on the arm, when it immediately became general. This lasted about half a minute. At 5.30 A.M. he had a second convulsion similar to the above and lasting about the same length of time. Between and after these convulsions he slept. At 8 A.M. the condition of the patient was good with the exception of the pulse, which was full and bounding. In addition to the calomel and Dover's powder, tincture of veratrum viride two drops and bromide of sodium twenty grains every two hours were ordered.

23d. Dressings changed, no pus; drainage-tubes clear; tincture of veratrum viride and bromide of sodium stopped.

26th. Calomel and Dover's powder stopped since slight mercurial stomatitis had developed, for which a gargle of chlorate of potassium and Listerine were given. From this time on, recovery was uninterrupted.

In closing my paper, I would not have it understood, from what I said in the beginning, that I am opposed to trephining for focal epilepsy, brain tumors, etc., for I am not; but I do not consider the results in these cases as brilliant as in cases of extra-dural hæmorrhage. Head injuries, both as regards their immediate and remote effects, are of interest to the neurologist as well as to the surgeon. I do not think it out of place to tabulate my rules for trephining in this class of cases:

1. In simple depressed fractures of the skull, with or without symptoms of compression.

2. In compound depressed fractures, with or without symptoms of compression.

3. In punctured or incised fractures, fractures of the orbital plate of the frontal bone, and punctures of the cribriform plate of the ethmoid, applying the trephine to the roof of the orbit at the inner angle, thus opening up the most dependent part of the cerebral fossa, thereby favoring drainage, which is the chief indication in this class of injuries.

4. Foreign bodies in the brain.

5. Impacted fractures in gunshot wounds.

6. In gunshot injuries of the skull.

7. In contusions of the scalp simulating depressed fracture I expose the wall of the cranium at the seat of the contusion, when, if I find a depressed fracture, I trephine. If a fissured fracture, I trephine if there is any hæmorrhage through the line or lines of the fracture.

CLINICAL MEMORANDA.

THERAPEUTICAL.

Ichthyol Ointment Externally in Inflammations of the Throat.—I have recently had occasion to treat a number of cases of an apparently œdematous sore throat, belonging in all probability to the same class of staphylo-amygdalo-pharyngeal inflammations as those to which Glasgow has particularly directed attention, and which he is doubtless correct in regarding as a variety of influenza. The point to which I now desire to call attention in regard to these cases is the great relief afforded by the inunction of a fifty per cent. ointment of ichthyol externally, beneath the angle of the jaw and along the border of the sterno-mastoid muscle. In three cases there were infiltration and tenderness in this region, which suggested the application. Its prompt and unexpected effect in relieving the pain which accompanied deglutition, suggested that the same measure might be usefully employed, even in the absence of external swelling. In most cases of sore throat, even simple follicular tonsillitis, there is usually more or less involvement of some of the fibrous tissues, whether of the submucosa of the subcutaneous connective tissue of the muscular sheaths, or of the various planes of fasciæ.

The same relief followed in the cases without external manifestations, as in the others. I am inclined to a more extended use of the agent in this manner, and even to its topical application to the mucous membrane, with a view to ascertaining its true value. It is quite possible that this use of ichthyol is not novel, and I make no claims in that direction.

Solomon Solis Cohen, M.D.
219 South Seventeenth St., Phila.

HOSPITAL NOTES.

A NEW OPERATION FOR HERNIA; EXCISION OF VARICOSE VEINS; NEURECTOMY OF INFERIOR DENTAL NERVE.

Abstract of a Clinical Lecture delivered at the New York Hospital.

By ROBERT F. WEIR, M.D.,
ATTENDING SURGEON.

Dr. Weir presented to the class a patient on whom he proposed to perform the usual operation for the radical cure of hernia, *i. e.*, to cut down upon the sac, return its contents into the abdominal cavity, then ligate and remove the sac at the internal ring. In addition to this, he introduced a novel feature, consisting in the use of a bone plate, which would more effectually close the ring. The plate of bone was removed from the scapula of a recently killed dog, and a semicircular opening was cut out of its upper surface, so as to protect the spermatic cord from undue pressure. Several small holes were punched in the plate, which was thoroughly disinfected and introduced into the wound.

In these operations, which, in the separation of the sac from the cord, sometimes require careful dissection of the fasciæ, by tearing layer after layer, it is important before attempting to close the wound, to examine the tissues carefully, and make sure that those remaining are in a condition to survive the manipulation.

The next case was one of extensive varicosities of the leg and lower part of the thigh, which demanded more radical treatment than simple or multiple ligation. In these cases, the deeper set of veins is also varicose, and hence, if only the external vein be occluded, there is no more relief than results from removing the tension of the skin, and the patient is still annoyed, although not so much, by the stretching of the deeper parts. In Dr. Weir's experience, the best results have been obtained by the employment of what is known as Marshall's method, or resection of a long strip of the veins. Since the advent of antiseptics, this method has been more frequently resorted to, and usually with good results. The operation necessitates a long wound, and owing to the impaired vitality of the skin from prolonged tension, there is not infrequently a small track of suppuration along the wound, which delays the healing process.

In the present instance, the course of the veins was mapped out with aniline before applying the Esmarch bandage, in order to furnish a guide for the subsequent incisions. The vein in the upper and inner part of the leg, and extending up along the thigh, was then carefully exposed, and about eight inches of it excised, after applying a ligature above and below this portion, and to numerous branches issuing from within the fasciæ to the venous track. The same procedure was adopted with the smaller varicosities in the middle third of the leg.

Another case of interest was one of long-standing neuralgia, affecting the left side of the lower jaw, and particularly severe along the anterior distribution of the inferior dental nerve. There was also some pain experienced in the parts supplied by the auriculo-temporal nerve; but as this was only occasionally present, it was hoped that the operation of neurectomy on the inferior dental nerve would relieve the pain in both situations.

A section of the inferior dental nerve in its upper portion presents considerable difficulty. The operative field on the inside reaches from the dental foramen up to the foramen ovale, a distance of only about one inch, in a region which is not easy of access; and the gustatory nerve splits off from the main nerve, and remains in close proximity to the inferior dental. The inferior dental nerve can be reached best in its deeper path by dividing and turning down the temporal muscle, with or without section of the zygoma. A division of the lower jaw bone, as advocated by Mikulicz, gives ample room, and sometimes allows one to see up as far as the foramen ovale. This is sometimes followed by non-union, but does not cause impairment of the function of the articulation of the jaw, which sometimes follows the first-named operation. Dr. Weir considered both of these methods too severe for this case.

Here, he said, we had the choice of two operations: one known as Paravicini's, or the internal operation, and the other, the external incision. The internal operation consists in opening the mouth widely, and making an incision about one inch long just above the wisdom tooth, along the anterior edge of the lower jaw, and through the periosteum, which is to be peeled off (this is important, or one will go astray), and then feeling for the edge of the dental foramen, or for the spine known as the point of Spix. Occasionally, one can recognize by sight, though more commonly by touch, the nerve as it passes into the foramen, where it can be seized, and from one-quarter to one-half inch removed. This is a region which does not easily admit of operative work, for the gustatory nerve is close behind, and is sometimes cut by mistake for the inferior dental nerve, or damaged during the operation. Dr. Weir had had, in one of his own cases, a very severe hæmorrhage during this operation, in which the patient lost six or eight ounces of blood, and which was only checked by plugging the cavity with iodoform gauze. The hæmorrhage recurred the same evening, and the patient lost four or five ounces more. The bleeding was so free, that it was not likely that it came from the inferior dental artery, but was probably caused by seizing and drawing forward the internal maxillary artery.

This internal operation is an ideal one, on account of its leaving no scar; but otherwise it is not satisfactory, and in this case the external method was adopted.

An incision was made, beginning about one finger's breadth above the angle of the jaw, to avoid the branches of the seventh pair, and was carried up anteriorly along the edge of the jaw-bone until it reached the anterior border of the masseter muscle. Then it was curved upward slightly on the cheek. With the handle of the scalpel, the soft parts, including the muscle, were readily detached from the bone; and in this way, with a blunt retractor dragging the tissues upward, Dr. Weir was able

to reach to a point about opposite the point of Spix. The bone was exposed and chiselled away, and after a slight hæmorrhage from the inferior dental artery had been controlled by pressure with a cotton-wrapped probe, the nerve was drawn down strongly, and about three-quarters of an inch removed. The masseter muscle was sewed to the edge of the jaw with catgut, a horse-hair drain inserted, and the skin wound closed by numerous fine black silk sutures. Black silk sutures are more easily seen when it is desired to remove them; and in order to reduce the scar to a minimum, it is important to introduce a great many of these sutures, and to begin removing them the following day. If there is much tension, two or three sutures should be left in on the third day, but otherwise, all of them should be out at that time.

Dr. Weir said that for the next day or two there would probably be a good deal of swelling of the face in the neighborhood of the wound, in which the parotid gland would in all probability participate.

MEDICAL PROGRESS.

Treatment of the Uric Acid Diathesis.—In the treatment of the uric acid diathesis DR. HENRY PICARD advises the administration of water in large quantities, believing that it is of use in assisting mechanically in the expulsion of uric acid that may be deposited in the kidney and in diluting that which may be contained in the blood. Water alone possesses such slight solvent effects upon uric acid that to it should be added an alkali. Lithia greatly augments the solvent power of water and may be given in the following mixture:

R.—Carbonate or citrate of lithium 15 grains.
Pulverized sugar . . . 1½ drachms.
Citric acid . . . . 3½ "
Bicarbonate of sodium . . 4½ "

Mix and divide into sixteen powders, of which one should be given in a glass of water four times daily.

The solvent effects of the potassium salts are also well marked and they may be administered thus:

R.—Bicarbonate of potassium . 1½ ounces.
Citric acid . . . . 1 ounce.
Water . . . . . 12 ounces.—M.

One ounce of this in three or four ounces of water makes an insipid solution that may be given even to children.

Some persons do not tolerate the alkaline carbonates well and, for such, the phosphate of sodium, administered in doses of from thirty grains to two drachms, is an efficient substitute.

The alkaline benzoates are also excellent solvents, and change the insoluble uric acid into the soluble hippuric. The benzoates of sodium and calcium are perhaps the best and may be administered in solution or in pill form in doses of from three to thirty grains. Benzoic acid may also be used, the following being an excellent formula in which to administer it:

R.—Benzoic acid . . . 15 grs. to 1 drachm.
Phosphate of sodium . 2½ drachms.
Syrup . . . . 7 "
Water . . . . 3 ounces.—M.

One-fourth to be taken at a dose.—*Journal de Médecine de Paris.*

Iodoform in Surgery.—The true position of iodoform as a surgical dressing has long been questioned. On the one hand are the surgeons who declare that it is a valuable antiseptic; on the other, are the mycologists apparently proving by laboratory experiments that it has little or no antiseptic power. In the *Annals of Surgery*, January, 1890, MR. A. ERNEST MAYLARD, of Glasgow, records an elaborate series of observations upon the influence of iodoform on bacteria, which seem to prove that iodoform in great excess has a germicidal effect upon the microbes of pus. Where the microbes are in abundance, some retarding influence appears to be exercised by iodoform upon their growth and even some diminution in the numbers which subsequently develop; but, if the number present be large, no germicidal effect is observed.

The general result of this series of experiments seems to show that iodoform has some distinctive power, and that its supposed or acknowledged value in surgery is borne out by experiments in the laboratory.

It may fairly be assumed that where iodoform is added to a wound, it will be largely in excess of any microbes present, and, therefore, precisely in the position in which the experiments seem to indicate that its antiseptic power lies.

As compared with many other much more powerful antiseptics, the special value of iodoform must rest upon its prolonged action. Solutions are absorbed, or carried away by the discharges, whereas iodoform remains as an almost permanent application. So that it is not infrequent to find, on the removal of a dressing, some weeks after its original application, the iodoform still on the surface of the wound, and as active—if the pungency of the odor may be accepted as a criterion of the continuance of its antiseptic power—as when first used.

[These observations do not support the conclusions of Tilanus (*Centralblatt f. Chirurgie*, January 4, 1890), whose experiments convince him that iodoform has a certain amount of influence in retarding the growth of tubercle bacilli, but that in fresh wounds and non-specific suppuration it is only useful as a dry protective.—ED.]

Creasote in the Treatment of Chronic Gonorrhœa.—DR. BREIMA recommends in the *Riforma Medica* the following injection for chronic gonorrhœa:

R.—Creasote . . . . . 10 minims.
Fl. extr. of hamamelis, Fl. extr. hydrastis canadensis . . } of each 15 "
Rose water . . . . 4 ounces.—M.

This should be slightly diluted with warm water before using.

Benzoate of Bismuth in the Treatment of Chancroids.—DR. FINGER has treated in the past eighteen months sixteen cases of soft chancre with local applications of bismuth benzoate. In each case the surface of the sore was thoroughly washed, a thin layer of the benzoate applied by means of a soft brush, and the whole covered with cotton held in place by an adhesive strap or bandage. The dressings were changed once or twice in twenty-four hours. The applications, particularly the first, were followed by slight burning and prickling sensations, which, however, were never severe. No inflammation was pro-

duced by the drug, and in twelve of the sixteen cases the results were excellent, the surface of the ulcer becoming healthy and the discharge of pus checked by the third or fourth day, so that simple dressings were sufficient to produce cicatrization. In five cases the effects were not so prompt, but even in these the duration of treatment was shorter than with the methods usually employed.—*Internationale klinische Rundschau*, January 5, 1890.

Operation for the Deformity of Prominent Ears.—In the *Annals of Surgery*, January, 1890, Professor Keen describes a new operation which he has recently performed for the common deformity of prominent ears. The operation consisted in removing from the long axis of the posterior aspect of the auricle a long oval piece of skin, the cartilage being laid bare by the dissection. A strip of cartilage of the same length, but narrower and V-shaped on cross section, was then removed, taking great care not to cut through the skin on the opposite side. In the left ear three catgut sutures were introduced through the cartilage in addition to those in the skin. On the right side reliance was placed entirely on the sutures through the skin. The result was equally satisfactory on either side. The two operations, performed at the same time, were attended with very free bleeding, which, however, was easily controlled. The stitches were not removed until the tenth day. The result was perfectly satisfactory.

Œdema as a Symptom of Pneumonia.—Dr. Stembo, in the *Berliner klinische Wochenschrift*, No. 40, 1889, calls attention to the occurrence of fugitive œdema in the course of acute diseases as an indication that pneumonia is about to set in. The œdema appears usually twelve to twenty-four hours before the physical signs of pneumonia. It is not always distinct, and often it is only by the closest attention that it can be detected, and that usually on the lower lid. It is more marked the weaker the patient, the longer the primary disease has lasted before the onset of the pneumonia, and the higher the temperature in the course of it; whilst a free use of antipyretics is not without influence in preventing it. Further, it is more evident on the side corresponding to the pneumonia, or, indeed, may be confined entirely to it. In children, and in weak and unconscious persons, the œdema is found on the side or in places which are most dependent. It often passes away in twenty-four to thirty-six hours, and seldom remains after three or four days. If it remains longer and cannot be removed by proper remedies, it is of grave import. That it is not due to renal complications is shown by the absence of casts in the urine, while only in a few cases are traces of albumin present. Stembo gives three examples out of a number of cases in which he has observed this symptom. The first was a child, twenty months old, suffering from enteric fever. On the tenth day slight œdema, especially of the right side of the face, but of the whole body as well, was observed. The temperature was 104°, pulse 148, and respiration 56. Extensive rhonchi were heard over the lungs, but no bronchial breathing; and there was no dulness. Next day dulness showed itself in the two lower lobes of the right lung with bronchial breathing. On the fourth day from this the œdema had gone, and two days later the lung had cleared up. In the second instance, that of a woman of fifty-five, suffering from typhus, œdema of the face appeared on the eleventh day; the same evening pneumonia of both lower lobes set in, and death followed in two days. The third case was one of bronchitis in a seven-months' old child. After seven days capillary bronchitis occurred; on the fifteenth day œdema of the face and dorsum of the feet appeared, followed the succeeding morning by catarrhal pneumonia of the left side; here the œdema began to disappear in three days, and was entirely gone before the pneumonia cleared up. This phenomenon is explained by the observer as mainly due to the weakness of the heart which takes place in illness of long standing. The onset of the pneumonia increases the work of the enfeebled organ, and its temporary failure is shown by the fugitive œdema.—*The Practitioner*, January, 1890.

Pseudo-angina Pectoris.—Dr. Dreschfeld, of Manchester, divides pseudo-angina pectoris into the hysterical, neurasthenic, gouty, and gastric forms, and the form due to excessive use of tobacco. According to the author, hysterical pseudo-angina pectoris is distinguished from true angina by the following points:

1. The age of the sufferer. Persons suffering from hysterical angina are young, as a rule, but *true* angina may occur in young females.

2. The attacks occur not after violent exertion, but often without a palpable cause, and in some at regular intervals.

3. The radiation of the pain is along the sternum and along the insertions of the diaphragm at the back. There is often marked hyperæsthesia of the skin over the left mamma, where there is occasionally a distinct hysterogenous zone.

4. There is almost always marked dyspnœa, and the vaso-motor phenomena are very prominent.

5. The patient shows a great deal of excitement, and there is not the anxious expression of countenance characteristic of true angina.

6. The coexistence of other hysterical symptoms, such as hemianæsthesia, contraction of the field of vision, hystero-epileptic attacks, etc.

7. The absence of any signs of heart disease.

Dr. Dreschfeld has seen within the last three years several well-marked cases of the neurasthenic variety, the prominent and characteristic features of which are as follows:

1. The attacks come on without any muscular exertion; in one case they came on almost every morning on rising, and in another case after worry or mental trouble.

2. The attacks are short. The cardiac pain is not very great, but there are marked pallor and irregularity of the pulse which often last for days.

3. The symptoms improve on walking or other slight muscular exercise.

4. The attacks are often either preceded or followed by insomnia.

In the form caused by tobacco the anginal attacks are preceded by an irregular, occasionally intermittent, pulse, by palpitations which persist for some time, and in the attack itself there is pain, usually limited to the heart, and great oppression. The attack is followed by pallor and sweating, and the pulse may then become

slow, and show increased arterial tension, or remain quick and intermittent for some time.

The symptoms disappear as soon as the patient gives up smoking. In considering this form of angina, one has, however, to bear in mind that occasionally excessive smoking may lead to atheroma and to affections of the myocardium and valves of the heart, and thus true angina may occur in chronic nicotinism.

In gout we often meet with true angina, yet pseudo-angina does occur, and here again the absence of cardiac hypertrophy and of atheroma will assist us in the differential diagnosis. The attack is characterized by a more limited pain over the heart, by general vaso-motor disturbances, and especially also by an irregular and intermittent pulse, which may last for many weeks or even months.

Gastric and intestinal affections produce anginal attacks in a reflex manner. Palpitations, an intermittent and irregular pulse, with more or less dyspnœa and general discomfort, are often noticed in dyspeptic persons and in affections of the liver. Occasionally, however, we have in these diseases pseudo-anginal attacks.

These attacks are characterized by the following features: They come on after meals; there is often epigastric pain, with associated pains in the back from the fourth to the sixth dorsal nerve; the anginal pain is præcordial, rarely substernal, and not so severe as in true angina; the pulse is irregular; there is pallor, often with profuse sweating. The attack usually lasts several hours. —*The Practitioner*, January, 1890.

Causation and Treatment of Rickets.—KASSOWITZ has recently put forward at some length his views on the etiology of rickets. The old theory of a deficiency of lime salts in the food has already been given up, though it is admitted that unsuitable food and chronic diarrhœa may keep up the existing disease. Pathology shows us that the bones are not simply deficient in lime, but that a condition of inflammatory hyperæmia exists in the affected parts. This is the essential element of rickets. As regards the theory that disturbed digestion is the cause of rickets, statistics from Vienna by Kassowitz, and from Christiana, Munich, and Kiel, by other authors, prove that rickets is most prevalent in the spring, reaching its maximum in May and June, and then declining to its minimum in November, whereas digestive disturbances are most prevalent in summer and autumn. Statistics also show the evil of close confinement in winter. A long residence in closed rooms, and the breathing of impure air, seem to be the most potent factors in the causation of rickets. Hence the rapid recovery on removal of patients to the seaside or mountains. If this hygienic treatment cannot be adopted, help must be given in other ways. Children should be sent out properly clad into the fresh air daily. Lime salts should not be given—ordinary food contains plenty of lime—nor should starchy foods be restricted and a meat diet advocated; the former are by far the most suitable for children. Acting on Wegner's discovery that phosphorus in small doses restricts the formation of vessels in the growing bones of young animals, Kassowitz advocates its exhibition in cod-liver oil as a means of overcoming the hyperæmia of the bones. The dose of phosphorus given is $\frac{1}{150}$th of a grain in a teaspoonful of oil. This treatment is already in use, and deserves a still more extensive trial. But, after all, hygienic measures must take the first rank in importance, for the disease is plainly one of defective hygiene.—*British Medical Journal*, January 11, 1890.

The Use of Calomel in Phthisis.—DR. DOCHMANN employs calomel in the treatment of pulmonary phthisis, particularly in the early stages, and claims that his results are good. He prescribes it in pills according to the following formula:

R.—Calomel . . . . . 8 grains.
Pepsin . . . . . 50 "
Tincture of opium . . . 30 drops.
Ext. of phellandrium, sufficient quantity.—M.

Make into 60 pills.

On the first day of treatment 12 pills (2 pills every two hours) are to be administered; on the second day 10 pills; on the third day 8 pills. After this the patient may take 6 pills daily, with occasional periods of intermission if not well borne. If hæmoptysis occurs, ergotin should be added to the pills; if cough is violent, extract of hyoscyamus.—*Prager medicinische Wochenschrift*, January 22, 1890.

An Application for Burns.—NIKOLSKI employs the following mixture as an external application in burns of the first and second degrees:

R.—Tannic acid, Alcohol, Ether . . . of each 10 parts.
Ether . . . . 80 " —M.

—*Deutsche medicinische Wochenschrift*, January 16, 1890.

Incompatibilities of Bismuth Subnitrate.—Subnitrate of bismuth is frequently prescribed in mixtures with bicarbonate of sodium, the combination of the two causing a slow effervescence, which sometimes bursts the bottle containing them. Again, the subnitrate with mucilage of tragacanth forms in a few hours a thick clot, which will hardly pour from a bottle. Both these results are explained by the fact that subnitrate of bismuth, though basic in constitution, is acid in reaction, and readily parts with its acid, especially in the presence of an alkaline carbonate. With bicarbonate of sodium and water, the subnitrate changes to carbonate, nitrate of sodium being formed and carbonic acid liberated. It is obvious that in such a mixture a patient would be taking mainly carbonate of bismuth and nitrate of sodium, the important antacid properties of the sodium salt being lost. For these reasons it is best to prescribe *carbonate* of bismuth, which is compatible with alkaline carbonates, does not thicken mucilage, and from its comparative lightness remains longer in suspension than the subnitrate. The following is a very satisfactory mixture:

R.—Carbonate of magnesium, Carbonate of bismuth of each 15 grains.
Tincture of nux vomica . . . 5 minims.
Chloroform water (Br.) . . . 1 f℥.—M.

To be taken in one dose.—*Illustrated Medical News*, January 25, 1890.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

DELIVERY BY UTERINE EXPRESSION.

THE employment of pressure on the fundus of the uterus through the abdominal wall, to expedite a tedious labor, is a custom as old as the world. Dr. Engelmann, in his most interesting and valuable work, *Labor Among Primitive Peoples*, describes how it is resorted to in some form in almost every labor among uncivilized races, and in our own time it is well known that midwives in the far East resort solely to external pressure in conducting labor. Although often practised with seeming brutality, which must surely have been a not infrequent cause of death, yet its widespread and perhaps instinctive employment suggests that the method is not wholly devoid of usefulness. Bearing in mind the danger of rupture of the uterus and other dangers consequent to its employment, it should not, we think, be totally excluded from the obstetric procedures of the present day. The older authors since Albucasis and Paré have recommended light pressure over the fundus to hasten delivery, and no obstetrician will question the judicious application of the Credé method of placental delivery. The same may be said of pressure through the abdominal wall to assist the after-coming head through a normal and even contracted conjugate, as has been recommended by Martin, Charpentier, and others.

In 1867 Kristellar, and in 1872 Suchard, went so far as to advise the employment of uterine expression to dilate the cervix and overcome spasmodic contraction of the os. The verdict of the profession, however, is that such a procedure is dangerous. To terminate a tedious labor forceps or version is certainly more rapid and less harmful. Nevertheless, a case reported by M. Grynfeltt, in the *Gazette Hebdomadaire des Sciences Médicales*, clearly demonstrates that circumstances may arise when it may be necessary to "push the fœtus out of the uterus instead of extracting it" (Barnes). Grynfeltt saw the case referred to in consultation. A multipara, in labor thirty-nine hours; L. O. A.; prolapse of left arm had prevented engagement of the head; os completely dilated; membranes unruptured. While explaining to the family the necessity of performing the operation of version, the membranes suddenly ruptured, the cord prolapsed, and the head entered the pelvic cavity. Forceps were not at hand, and to save the life of the child uterine expression was quickly resorted to, the two hands grasping the fundus, thumbs in front, as in placental expression after Credé. In two minutes the child was delivered alive, without subsequent discomfort to mother or infant.

Similar expression has been successfully employed in the management of miscarriage. In reckless hands the method is not devoid of danger, yet employed with ordinary skill and intelligence it deserves a place in obstetric practice to meet the not uncommon emergency described.

THE MALARIAL HÆMATOZOON.

AMONG those who have contributed to our knowledge of malarial infection the name of Laveran will always be preëminent, notwithstanding the fact that in the bibliography of the subject it has to be sought for among a host of others. A discovery is no sooner announced than it is subjected to the most rigid scrutiny, and perhaps added to or subtracted from until the discoverer may think himself fortunate if the entire credit of his research has not been divided by numerous investigators who have done little more than follow in his footsteps. The thoroughness of Laveran's first investigations was such as to preclude them from this fate, and, therefore, the work which they suggested to others was little else than confirmatory. Notwithstanding the almost unique fact of Laveran's undisputed claim to priority in this matter, it is, perhaps, not too much to say that during the last five years many hundreds of

medical students have carried away with their diplomas the conviction that their medical teacher who had given such brilliant demonstrations of the *plasmodium malariæ* was the real discoverer of the parasite.

Such an error might be due to no actual fault on either side, but solely to the lazy constitution of the average mind, which hates investigation. For such reasons we welcome Laveran's latest communication (*Archives de Médecine expérimentale et d'Anatomie pathologique*, January 1, 1890), in which he discusses: 1, the nature of the malarial parasite; 2, the manner in which it gives rise to the symptoms of malaria; 3, the technique of its study.

The question whether the well-known appearances of malarial blood are due to a single polymorphous parasite he answers in the affirmative, and for the following reasons: First, it is highly improbable that the different symptoms of malarial poisoning could be due to several parasites of different species, for these symptoms are constantly interchanging, while the unity of paludism, both from the clinical and anatomical points of view, is unquestionable. Secondly, since its discovery, the malarial organism has been proved to be one of a large family of polymorphous hæmatozoa, some of which bear the closest resemblance to it. This is particularly the case with the hæmatozoa of birds, which have been so closely studied by Danilewsky. Laveran was so struck with this resemblance, although he points out certain differences between them, that he endeavored to propagate the plasmodium in the blood of birds, but without success.

The following *résumé* embodies the chief facts concerning the malarial hæmatozoon, and leads irresistibly to the conclusion that it is the morbific agent of paludism in all its varieties:

1. The parasite has been found in all countries in the blood of those affected with the malarial poison, and the numerous descriptions of its appearance are remarkable for their identity.

2. The parasite has never been found in the blood of those not affected with the malarial poison.

3. The development of the parasite is intimately connected with the production of melanæmia, which is the characteristic malarial lesion.

4. The salts of quinia cause the parasite to disappear from the blood, and this takes place synchronously with the cessation of the fever.

5. Malarial disease has been transmitted from one person to another by injecting into the veins of a non-malarial individual a small quantity of blood containing the parasite.

The mode of life of the malarial organism outside of the human body is as yet unknown, and it seems probable that its aspect under such circumstances is different from that which it presents in the blood of man. It is possible that, in one phase of its existence, it may be the parasite of some other animal or of a plant, and Laveran suggests the possibility that the mosquito may play a *rôle* in its transmission.

The manner in which the hæmatozoon gives rise to the symptoms of malarial poisoning is a question of great interest. Laveran believes that its action is both vital and mechanical. In virtue of the former it destroys the red corpuscles, and the extent of this destruction is shown by the anæmia and the accumulation of pigment in the vessels and tissues.

The nervous symptoms—such as the chill, fever, headache, etc., are due to irritations of the cerebral nervous system.

The failure of all attempts to cultivate the malarial organism has been advanced as an argument against its parasitic nature, but no better success has attended the culture experiments in the case of the filaria sanguinis.

The hæmatozoon malariæ does not belong to the class of schizomycetes, and, therefore, it is not surprising that its behavior is different from that of micrococci and bacilli.

These are the essential facts concerning the malarial germ as set forth by its discoverer. They are of the greatest practical interest, for already, in numerous instances, the diagnosis of some of the most obscure forms of malarial poisoning has been made by the detection of the parasite which is its constant attendant.

NEW INVENTIONS.

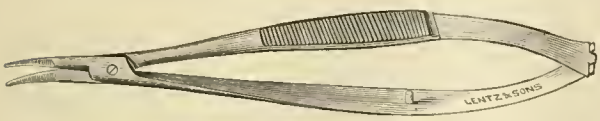
SCISSORS FOR TENOTOMY.

BY EDWARD JACKSON, M.D.,
PROFESSOR OF DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC.

THE ordinary scissors, with ring handles, require for any given position of the scissors that the hand shall be brought into a certain position; there is only one relation of hand and scissors that gives the operator good control of his instrument. When doing a tenotomy of one of the recti muscles of the eye, to get a smooth cut in the proper direction the blades of the scissors must have a certain position and direction, relative to the insertion of the tendon and the eyeball. But the eyeball is capable of free rotation; and does rotate often in the course of

the operation. And with the ring-handled scissors, to keep just the right relation between the blades and the tendon, each movement of the eye must be followed by a corresponding, but greater, movement of the hand and arm. And no matter how well you may arrange your patient and plan the little operation, you will find before it is over that you are getting in your own light, or your fingers or the assistant's, or the patient's head, is very much in the way.

This difficulty is largely avoided by using scissors with spring or forceps handles, like those shown, two-thirds the natural size, in the accompanying cut. These



can be readily grasped, and satisfactorily used with the hand in any one of many positions with relation to them. So that it is possible to adapt the blades to any position of the eyeball, without much change in the position of the hand.

The scissors represented, which have been made for me by Charles Lentz & Sons, of Philadelphia, conform in certain other important respects to the requirements of a tenotomy operation. The joint is particularly broad and hrm, to prevent over-riding; yet the blades are sufficiently delicate. The blades are but slightly curved, but this curve is near the point, where it is needed. The points are as blunt as is compatible with easy introduction, the blades are not unnecessarily long, and are so formed that the line of the cutting edge passes near the rivet, and a comparatively slight spreading of the points gives sufficient length of blade to sever the whole width of the tendon, while they exert very little of the forward thrust that tends to push the tendon off the hook, allowing it to escape uncut.

CORRESPONDENCE.

INTESTINAL ANASTOMOSIS.

To the Editor of The Medical News,

Sir: It seems to me that the subject of intestinal anastomosis should be treated with great care. Senn's numerous operations[1] on animals were made, not only to ascertain if the operation could be made successful for the hopeless condition of complete stenosis, but also to find what method would be most surely successful.

The result of his laborious experiments, laborious because conducted with extreme antiseptic precautions and with a variety of material, may be told in a sentence:

"Partially or completely decalcified bone plates hardened in alcohol, *remain firm* for a sufficient length of time to answer the purpose of retentive measures until firm adhesions have formed between the serous surfaces held by them in approximation. In a few days the disks completely disappear by softening and disintegration. The plates, when properly fixed in their places and tied together with sufficient firmness, not only *coaptate an extensive area of serous surface*, but they at the same time secure *perfect rest* for the parts it is intended to unite until firm adhesions have formed."[1]

This is the whole matter in a nutshell; the fewest number of apposition sutures, not more than four in the plates; this to save time and thus prevent shock; coaptation of an extensive serous surface which secured perfect rest of the parts to be joined for a time sufficient for union.

Senn's numerous operations on animals, with a number on human subjects, show magnificent results. If, after a suitable series with the quickly softening catgut plates or yielding rubber rings an equal success is reported, one might be willing to trust them for what at best is an appalling necessity.

To Dr. Senn the trouble of having prepared one or ten bone disks is not the question; but, What is to be the result for a human life? Standing at his side and seeing him insert the plates in a human intestinal tract the question comes with tremendous force, Will the coaptation be perfect, or will there be a leak and peritonitis and death? Can it be believed that a segmented flexible rubber tube, as has been recently described, impinging only at its convexity will as surely resist tympanitic and other pressure as will the broad firm grasp of disk surfaces?

The operation is a new one; a great thinker has wrought it out with almost infinite pains; it offers relief to a class of cases who before were without hope. Why be in such haste to improve upon it before it is fairly tested by surgeons generally? Ira Manley, M.D.

Markesan, Wisconsin.

DETROIT.

To the Editor of The Medical News,

Sir: At a recent meeting of the Detroit Medical and Library Association, Dr. Flinterman presented a very interesting specimen, embracing the two kidneys from an individual who died of uræmic poisoning. The kidneys were very large and their substance was almost completely obliterated by the formation of numerous cysts.

Dr. Mills read a paper on "Heart Diseases," which called forth a prolonged debate.

At a subsequent meeting, Dr. Rowley exhibited a very rare specimen, secured post-mortem, which showed the two kidneys united by a fleshy band, and giving the entire mass a horseshoe shape. The mass uniting the two kidneys will be examined microscopically to determine its histological structure.

Dr. Campbell exhibited a scirrhus of the lesser curvature of the stomach with perforation of the posterior wall. Death in this case was sudden, and presumably due to perforation and shock.

Dr. T. A. McGraw has recently returned from a five-months' sojourn abroad, and has resumed work in the college. He was banqueted a few evenings since by the students and members of the faculty.

THE CONTAGIOUSNESS OF INFLUENZA.

To the Editor of The Medical News,

Sir: The following observations bearing upon the question of the purely contagious nature of the recent

[1] Experimental Surgery, Senn, page 422.

[1] Loc. cit., pp. 446 to 455.

epidemic of "grippe," may be of some interest to your readers:

Fearing an attack of the prevalent influenza might prove disastrous to many of the invalids at the Adirondack Cottage Sanitarium, the place was quarantined as soon as the epidemic appeared in the neighborhood. The sanitarium is only a mile from the village, and at this date, January 30th, no outbreak of the disease has taken place there, while it has attacked the great majority of all the people living in the surrounding country, as well as the visitors at the hotels and boarding-houses. I am not aware of any other case being on record where quarantine has proved in any degree successful in averting epidemic influenza.[1] E. L. TRUDEAU.

COMBINED METHODS OF TREATING AN ASPHYXIATED INFANT.

To the Editor of THE MEDICAL NEWS,

SIR: On August 10, 1889, I was asked to aid a midwife in the case of Mrs. C., near Wayne. Upon arrival the head was found to be well down and the parts in good condition, there being no real impediment to the delivery which, without instrumental aid, occurred within ten minutes. The mother, well developed and healthy, was not lacerated, the placenta was slightly adherent to fundus. The infant—male, eight and one-half pounds—was pallid (not cyanosed) with normal pulse and both chest-walls collapsed. A few moments after birth it elevated the eyelids, rolled the eyeballs as if observing the surroundings, and then closed the lids. Afterward it remained limp and pallid, with as good a pulse and fair a temperature as the condition warranted, until respiration took place, about an hour later. All the usual methods employed to excite respiration were thoroughly tried, but without avail—the lungs remained collapsed. After fifty minutes spent in this endeavor, I essayed, and readily succeeded in, intubating the larynx.

The following are the details, so far as they relate to the modification of the method in vogue in France: A nozzle of my obstetrical syringe was inserted into the end of the male catheter, the air with which the syringe was filled being drawn each time through a thick pad of antiseptic gauze moistened with twelve per cent. hydrogen dioxide. The air was cautiously pumped into the lungs, the arms at the same time being elevated. On withdrawing the nozzle, the lowering of the arms and pressing them against the sides expelled the air. Thus the two methods, of Sylvester and insufflation, were employed simultaneously. In twenty minutes the respiration became automatic. To-day the child is apparently healthy in all respects.

Among some 900 cases at full term, the above is the only instance in which, when the case demanded it, some one of the usual methods did not suffice.

G. E. ABBOT.

BRYN MAWR, November 29, 1889.

NEWS ITEMS.

Tri-State Sanitary Convention.—Arrangements have been completed to hold a Tri-State Sanitary Convention at Wheeling, W. Va., February 27 and 28, 1890. Representatives will be present with papers and addresses from Pennsylvania, West Virginia, and Ohio. The object of the convention is to consider the question of floods and their results from a sanitary standpoint, and the best methods of managing the sanitary interests of a given community after such a calamity.

Owing to the mutual relations held by these three States, with reference to large rivers, and the numerous towns that are annually affected by floods, it has been thought wise to hold a convention for studying how best to manage the sanitary interests of cities and towns so affected.

Every person interested, directly or indirectly, in this important subject is earnestly requested to be present to assist in discussing the papers, and to add whatever information he can to the solution of these practical and most important questions, concerning as they do the health and lives of thousands of citizens of these three great commonwealths annually.

Reduced rates of transportation have been secured over all lines controlled by the Central Traffic Association in the three States named, on the certificate plan. Application has been made to the Trunk Line Association for like favor.

Stevens' Laboratory Prizes.—The following has been received from the Stevens' Laboratory, Maine:

From a desire to verify his own researches as to the causes of failing nutrition in aged organisms, the undersigned hereby offers three cash prizes of $175, $125, and $100 for the best three comparative demonstrations, by means of microscopical slides, of the blood capillaries in young and in aged tissues, canine, or human.

By young tissues (canine) are meant tissues from animals between the ages of one and three years.

By aged tissues (canine) are meant tissues from animals not less than twelve years of age.

By young tissues (human) are meant tissues from subjects between the ages of ten and twenty years.

By aged tissues (human) are meant tissues from subjects not less than sixty-five years of age.

While a preference will be given to demonstrations from human tissues, it will be possible for work in canine tissues to take the first, and, indeed, all of the prizes. But of two slides equally well done in all respects, one canine the other human, the latter will be given the preference. Canine tissues should be from large animals.

Twelve slides from young and twelve from aged tissues must be submitted by each competitor, together with a full description of the subjects, methods pursued, and every detail and circumstance which is likely to throw light upon, or account for any peculiarity. The slides are for comparison as to the condition of capillary circulation, the young with the old, and should be in numbered pairs, or groups from the same kind of tissue. The term tissue is used in a general sense—*e. g.*, pulmonary tissue, hepatic tissue, renal tissue, osseous tissue, muscular tissue, nerve tissue, alimentary tissue, etc.

No particular schedule of methods for injection, or staining, will be insisted upon, and no more definite directions or explanations will be given.

The slides, carefully packed and boxed, together with descriptive manuscript, can be sent by mail.

It is stipulated that the demonstrations which receive

[1] A note received February 8th from Dr. Trudeau states that no case of "la grippe" has yet occurred at the Sanitarium.—ED.

the prizes shall become the property of the subscriber, for publication. All others will be returned, if desired.

No pseudonyms required. Accompany slides, in every case, with (real) name and address. Unless of known reputation as a biologist, a reference is respectfully solicited.

Reservation: no award will be made unless work of at least ordinary merit is submitted.

This offer is made on the first day of January, 1890, and will remain open until the twentieth day of August, 1890.

Slides and manuscript will be examined and receipted for as soon as received.

The prizes will be adjudged on the first day of October, 1890.

These nominal prizes are offered less in expectation of results from the money as an agent, than in the hope that the offer may furnish a *point d'appui* for really needed work. Besides professional observers and students, there are in the United States a large number of amateur microscopists of acute vision and undoubted talent, who are at present playing with microscopes as with toys, merely to see the curious or pretty things. The time has come to concentrate observation upon the one proper object of biology, viz., the renovation and prolongation of human life. Address C. A. Stevens' Laboratory, Norway Lake, Maine.

The License to Practise and Medical Testimony.—A recent decision in France states a general point of law affecting the medical profession in regard to its duties to the State, where a license to practise is issued. To the question, May a physician refuse to aid a coroner or other public official? the French decision says that the physician is in duty bound to respond to the summons of all judicial tribunals for the investigation of crime. No person may practise medicine or surgery save under authority of the law which prescribes what shall be his qualifications. This law, by virtue of which alone he has his legal status and existence, declares certain functions which none but the physician shall perform. From these legal premises the inference is inevitable that the law must look to the physician for the performance of those functions when a medico-legal investigation is required, as the physician is licensed for a public duty as well as for a private vocation. In other countries and states, where a definite license to practise is not granted, some other point of law must be found for the coercion of expert medical testimony, or for the creation of a special class of medico-legal experts.

Medical Lake, in the State of Washington.—Medical Lake, near the city of Spokane Falls, Washington, is a body of water to which many Western people are resorting to bathe, on account of its alleged efficacy in rheumatism and skin diseases. One of its properties is that it forms a lather when violently agitated or when rubbed on the skin. No fish or other varieties of life are found in its waters, and its appearance is muddy and repulsive. A town is springing up near the borders of the lake, to which excursion trains are to be run during the summer season.

Adulterations with Terra Alba.—The clay-eaters of the North differ from those of the South in the fact that they do not know that they are taking terra alba, and that it comes to them variously flavored with wintergreen, peppermint, etc. It is asserted by the *National Druggist*, as the result of a special investigation in connection with a lawsuit, that lozenges are made in enormous quantities of little else but white clay. The clay is compressed in moulds, and bound together by a little gum or gelatin, and immersed for a few moments in a syrupy bath containing the required flavor. This makes a very cheap form of confection which is largely consumed by children. The adulteration or substitution is also carried on to some extent in the manufacture of caramels; but in the case of the cheap lozenges the proportion of clay used is the highest possible consistent with their maintenance of shape. The Portland Board of Trade *Journal* has stated that there is an annual importation of terra alba amounting to 6000 tons, and that the only considerable use made of it is in the adulteration of the cheaper grades of candy.

The New York Charities in 1889.—The Annual Report of the New York State Board of Charities shows the reported amount of gratuitous medical and surgical relief by hospitals and dispensaries to have been 525,000 patients, of which 26,000 were treated at their homes, at an expenditure of $670,000. The estimated number of insane in the State was about 20,000, or 3.33 per thousand, on the basis of 6,000,000 as the population of the State. The report contains a protest against the erection by the State of any more buildings for the concentration of the insane, saying that the day of huge asylums has gone by, and that it is an extravagant misuse of funds to construct retreats and hospitals which cost $2500 per capita for shelter alone. It adds the statement that the weight of opinion among eminent alienists is adverse to the herding together of large numbers of insane persons. The entire receipts of the year for charitable and correctional purposes were $16,000,000, and the expenditures were $14,800,000; the total number of inmates of charitable and reformatory institutions was 67,780. The invested values of all institutions are over $57,000,000, of which $38,000,000 belong to incorporated benevolent associations.

A Hospital at Atlanta.—The citizens of Atlanta have determined to build a hospital as the most fitting memorial to the late Henry W. Grady, the favorite statesman of Georgia. It will, when built, bear the name of the Henry W. Grady Hospital.

Vacancies in the U. S. Navy.—In one of the circulars drawn up to explain a Navy reorganization bill before the Senate, an argument is based upon a comparison of the surgeons of the Army and Navy. In the Army there are always a number of applications for each vacancy; in the Navy there are several vacancies and no successful applicants. Last summer Secretary Tracy convened an Examining Board at the Navy Yard at Brooklyn, for the filling of nine vacancies among the naval assistant surgeons. Until a recent date no satisfactory candidates had been secured. A few candidates presented themselves, but could not stand the physical or other examinations. A Board has also been in session a longer period at San Francisco, by means of which one or two surgical vacancies have been filled. From this and

similar indications, it must be inferred that the young medical men who desire to secure a governmental surgeoncy are attracted to the Army in preference to the Navy; and it seems desirable that by new legislation the allurements of the latter service shall be enhanced by better rank, or better pay, or by both.

The Alvarenga Prize.—The College of Physicians of Philadelphia will award the Alvarenga Prize, consisting of one year's income of the bequest, to the author of the best memorial or unpublished work on any branch of medicine, the College reserving to itself the right to reject all essays not considered worthy of the prize, and that they will be received by the Secretary until June 1, 1890.

The Profession in France.—The number of practising physicians in France has been, of late years, steadily on the decrease. In that country there are, in accordance with the law of March 10, 1803 (19 Ventose, year XI.), two kinds of physicians: the doctor, and the health-officer—officier de santé—the latter corresponding to the English apothecary. The doctor, who, after a long course of study, has passed a rigid examination, has the right to practise in all the branches of his profession and in all parts of the country, whereas the officier de santé cannot practise outside of the department in which he has received his license, and is decidedly restricted in the exercise of his profession, being debarred, for example, from performing a major operation, unless in the presence and under the control of a doctor. It has been proposed by one of the Deputies, M. Chevandier, a physician, to abolish the officier de santé on the facetious ground that as no one is half-sick—demi-malade—there is no occasion for a half-doctor—demi-médecin. The proposition has called out a decided opposition from one of the French newspapers, which calls attention to the decrease in the number of practising physicians above mentioned, this decrease affecting both branches of the profession. For example, there are in France, at the present time, 29,795 communes destitute of physicians! The diminution is most marked in the case of the inferior branch of the profession, which numbered 7500 in 1847 and 3000 in 1889. In the article referred to, no attempt is made to account for a state of affairs which seems most anomalous to those whose country enjoys or suffers from an *embarras de richesse* so far as medical men are concerned.

The Indian Medical Journal.—By the death of Surgeon Charles Washington Deakin, of the Bengal Army, the *Indian Medical Journal* loses its editor and publisher, and it is said that the journal itself comes to an abrupt conclusion. Dr. Deakin died of enteric fever, in the Punjab, November 17, 1889, aged forty years. Although he had been less than ten years in the medical service, he left a brilliant record for surgical skill in several of the provinces of India.

Co-operation in Medicine.—A bill has been introduced into the New York Legislature, incorporating the Co-operative Medical Association of Brooklyn, with a capital of $1200. Its object will be to supply cheap attendance by means of coöperative physicians of a like grade. It is designed to meet the needs of the poorer class of patients who do not wish to resort to institutions of charity.

Examinations for Appointment in the Medical Corps of the U. S. Army.—An Army Medical Board will be in session in New York City, N. Y., from May 1 to 31, 1890, for the examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the Board will make application for the necessary invitation to the Secretary of War, before April 1, 1890, stating the place of birth, place and State of permanent residence, and enclosing certificates based on personal knowledge from at least two physicians of repute, as to professional standing, American citizenship, character and moral habits; also, statement of service in hospital from the authorities thereof is desirable. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a *regular medical college*, as evidence of which his diploma must be submitted to the Board.

Further information regarding the examinations and their nature may be obtained by addressing the Surgeon General, U. S. Army, Washington, D. C.

The pay of a first lieutenant of cavalry, or of a medical officer during the first five years of his service is $1600 per annum, or $133.33 per month. At the expiration of his five years of service he becomes, by virtue of that fact, a captain, and his pay is that of a captain of cavalry, $2000 per year, increased by ten per cent. for his years of service, viz., $2200 annually, or $183.33 monthly. At the end of his tenth year of service this rate of pay is increased by the service-addition to $2400 annually, or $200 per month, and after five years more the service-addition makes his pay $2600 aunually, or $216.67 per month. If he continue in the rank of captain, at the end of twenty years of service his monthly pay becomes $233.33; but about this time promotion to a majority is usually obtained, and a major's annual pay of $2500, with forty per cent. added, makes the monthly pay of the major and surgeon $291.67. Subsequent promotion, investing the individual with the rank of lieutenant-colonel, colonel, and brigadier-general, augments the monthly pay respectively to $333.33, $375.00 and $458.33.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING FEBRUARY 8, 1890.

Jones, W. H., *Surgeon.*—Ordered to the U. S. S. "Swatara."

Hudson, A., *Medical Director.*—Died, February 7th, at Mare Island Hospital, California.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

REMOVAL OF AN ANOMALOUS ABDOMINAL TUMOR.

A Clinical Lecture delivered at the University Hospital.

BY WILLIAM GOODELL, M.D.,
PROFESSOR OF GYNECOLOGY.

GENTLEMEN: The woman whom I show you this morning is thirty-four years old. She has a very large abdominal tumor, complicated with exhausting menorrhagia, but she does not suffer as much as her appearance and the size of the tumor would indicate. The tumor has been present for seventeen years; but it has increased much more rapidly and given much more trouble during the past year, so that she has now come here to see if it can be removed.

Before she was etherized, I explained to her that I could not be able fully to make up my mind as to what I should finally do, until I had made an exploratory incision. She was perfectly willing for me to do exactly as I thought best, so I have had her etherized, and will make an incision to see whether the tumor, after being tapped, can be removed. If it cannot, this exploratory incision will be closed, and the woman will have run comparatively little danger.

Upon making a digital examination some days ago, I found the womb wholly free from any attachments to the tumor, yet the cyst has adhesions which keep it firmly fixed. I now divide the abdominal wall, and upon coming to the tumor it looks like a malignant ovarian cyst, but I shall not stop to decide this point; besides, the microscope will be necessary before a final diagnosis can be made. This large piece of omentum which lies so formidably before me, presents a double adhesion to the tumor and to the abdominal wall, and, as it is important to cause as little bleeding as possible, I tie the whole piece of this omentum *en masse*, preparatory to tapping the cyst. While I am thus engaged—for it will take a few minutes—let me mention that the woman upon whom I performed a very difficult oöphorectomy before you last Wednesday is doing exceedingly well. She has not had a single bad symptom.

This tumor looks malignant, wonderfully malignant, and yet it may not be so, for appearances in abdominal tumors are often very deceptive. I do not wish to make this incision any larger than I can possibly help, so I diminish the size of the tumor by drawing off its contents. The contents, however, are not fluid, but a dark-red or grayish-black, pultaceous mass. This appearance does not lessen my fears regarding the malignancy of the cyst. In the wound I shall have to leave a drainage-tube, on account of the character of the tumor and of its adhesions, which are mostly omental and parietal. The tumor cannot be lessened in size, so I shall have to enlarge the incision; and, having now done this, I lift the tumor out before you. Its walls are very thick, the tumor seeming almost solid, and its weight, without the little fluid that escaped, is probably about fifteen pounds. I have to tie a number of omental veins, which run like earth worms into the tumor. Some bunches of them I tie *en masse*, and others singly.

This is the first time in my experience that a tumor like this one has lasted so long as seventeen years. It does not look like an ovarian tumor. I transfix the pedicle, tie it with the "Staffordshire knot," and remove the tumor. It is *not* ovarian, for here are both ovaries and tubes, perfectly healthy in every respect, and the pedicle of our tumor comes off from the broad ligament close to the left ovary. This is the most remarkable tumor that I have ever met with, and is, I fear, a malignant dermoid. But I have never before met with a dermoid cyst in the pelvic cavity which was not ovarian.

I now go to work to cleanse the abdominal cavity, and find that there is some vessel bleeding. As it comes from the torn surface of the omentum, I do not hesitate to tie the whole, and to cut off a large piece of it.

I now remove the sponges, cleanse them, and put them back. I again take a look at the ovaries, and find that they are perfectly healthy, which makes matters look better than if they also had been diseased. I come across some other pieces of omentum, and I do not hesitate to remove them if they are bleeding, or tattered and torn. This looks a little rough, but I am confident that it is the right thing to do. Moreover, you may ask, in connection with this: "Does it not increase the risk of sepsis or peritonitis to use so many ligatures?" I answer, Yes; they must do so to some extent, but less than the bleeding for which they were used. I have put in as many as sixty, apparently without any evil results, so that I do not think that they add much to the danger. There has been comparatively very little loss of blood here, except what was unavoidable from the congested state of the divided parts. I should have expected more hæmorrhage and menorrhagia from such a large and congested womb, though sometimes it happens that such is not the case. When I first examined this patient, had it not been for my previous experience in these matters, I should have concluded that it was a malignant tumor of the left ovary; but, as it had already lasted seventeen years, I was more inclined to believe it to be a pedunculated fibroid of the uterus.

Before putting in the sutures, I shall excise the navel; both because its tissue is thin and forms a poor cicatrix, and because it is a favorable seat for septic germs. When these sutures are *in situ*, I thoroughly irrigate the peritoneal cavity with warm water, and with my hands I paddle about the bowels, and wash out this cavity and Douglas's pouch, pouring in jugful after jugful until the water comes back clean. I know that this looks to you rough, and I would not have dared do it ten years ago.

But experience has taught me, and others, that it is not what goes into the peritoneal cavity, but what is left there to disintegrate and to cause sepsis, that is really dangerous.

While I am engaged in this irrigation, I shall take the opportunity of telling you that all the patients upon whom I have so far operated before you this session, have done well, except the woman who had, as I then told you, syphilitic ozæna. Her ovaries were removed, and she died in three days, from heart failure. I attribute her death to the fact that she had been an opium-eater, which, unfortunately, I did not know until after her death, and, possibly, the too sudden withdrawal of so powerful a customary stimulant from her at the time of such a dangerous condition, was too great a tax upon the system.

The instruments and sponges being now counted, the sutures are tied, and the wound closed, after being sure that all the water that I have poured in has come out again.

This corkscrew among my instruments—a suspicious object for a gynecological teacher to have—needs some explanation. I brought it with me to-day, thinking that I might have to use it in taking out the supposed fibroid tumor. By screwing it into a solid fibroid, we get an excellent hold which takes no room.

As my hour is up, I shall remove the woman to my private room, and apply the usual antiseptic dressings.

[At his Clinic two weeks later, Dr. Goodell informed the class that this woman's temperature had not been over 100° since the operation, and that she was then doing well in every respect.]

ORIGINAL ARTICLES.

THE CAUSE OF DEATH FROM CHLOROFORM.

BY H. C. WOOD, M.D.,
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS IN THE UNIVERSITY OF PENNSYLVANIA,
AND
H. A. HARE, M.D.,
DEMONSTRATOR OF THERAPEUTICS.

IN the *Indian Medical Gazette* for February, 1889, it is stated that a Commission composed of Dr. Hehir, Mr. Kelly, and Mr. Chamarette, assisted by the students at the Hyderabad Medical School, have made a series of experiments upon 128 full-grown pariah dogs, to ascertain the method in which chloroform causes death. It is further affirmed that the investigators varied the doses and the method of administering the chloroform in every way, and tested the value of artificial respiration by reviving the dogs over and over again, after breathing had stopped, and while the heart was still beating, and that they found that no matter in what way the næsthetic was given the heart became dangerously affected only when the breathing had ceased.

We have not had the opportunity of seeing the original report of this Commission, but learn from current medical journals that under the auspices of the Nizam of Hyderabad, Dr. Lauder Brunton, of London, has gone to investigate the matter. It is also stated in the *Lancet* that cablegrams have been received from Dr. Brunton affirming that the experiments of the Commission have been verified and their conclusions justified, and that as many as 450 animals have been used in the study of the question.

The surprising statements which have been made in the Indian journals and in the London *Lancet*, with the practical deductions which *apparently* follow upon them, seem to us of so great import as to demand the putting upon record of our own experience.

We believe that physiologists in general hold the opinion that when chloroform is given to the lower animals in a very dilute form, and gradually pushed, it causes by its action upon the nerve centres a paralytic relaxation of the muscles and at last death by paralysis of the respiratory centres; but that when it is administered freely in concentrated vapor by inhalation, or when it is injected in sufficient amount into the jugular vein, it kills by a paralytic arrest of the heart, the viscus stopping suddenly in its beat, and being found after death relaxed and incapable of reacting to stimuli. It has generally been believed that the danger from cardiac arrest by chloroform increases in direct ratio with the rapidity of administration; but that in animals, as well as in man, cardiac arrest sometimes occurs almost at once on the inhalation of the anæsthetic in small amount; or, in other words, that comparatively small amounts of chloroform have at times caused death by syncope, through direct action upon the heart. This we believe has been the teaching of all the instructors, both clinical and physiological, in the Medical Department of the University of Pennsylvania, and we desire to reiterate, as the result of our past experiences, that chloroform does, in the ordinary American dog, sometimes kill by paralyzing the heart, such paralysis accompanying or preceding, according to our past experiments, the arrest of the respiration.

It has been the custom of one of the authors of this paper, in his lectures before the University class, to demonstrate by means of the respiratory tambour, the mercurial manometer, and the kymographion, a continuation of respiratory movements after cardiac arrest through chloroform. Further than this, we have at various times in the Laboratory of Experimental Therapeutics, at the University, taken tracings proving the same facts.

Moreover, on experimenting with other drugs in the laboratory, the point at issue has been determined, because we almost invariably kill the dog which has escaped the drug being studied, with chloroform, whilst its artery is still attached to the kymographion, and the needle is still registering the play of the blood. We have sometimes given the drug intravenously, but in many cases we have administered it by inhalation of the concentrated vapor, and we have often noticed that death has been produced by primary cardiac arrest.

When chloroform is injected into the jugular vein it is carried first in its concentrated form to the right side of the heart, and when it is absorbed through the lungs it is carried directly to the left side of the heart. In either method of administration the anæsthetic reaches the heart in a concentrated form before it is scattered in the circulation and gets to the respiratory centres. This may have connection with the frequent early occurrence of cardiac arrest during chloroformization in the human subject, but we desire especially to emphasize the point, that in either method of administration the heart is first reached, and that in our experience there is no essential difference in the action of chloroform, whether it is given by inhalation or whether it is injected into the jugular vein.

As we use between us, in the laboratory of the University, many dogs yearly, a very large proportion of which are finally killed by chloroform, we may be excused for our past positive assertions that chloroform is a cardiac paralyzant and does kill dogs by a direct action upon the heart or its contained ganglia; especially since we have been strengthened in our opinion by the fact that Dr. Reichert, Professor of Physiology in the University, has reached results confirming our own, and has frequently demonstrated the same to the University classes.

The statements that have been recently made in the Indian journals and in the London *Lancet*, have led us to reëxamine the subject and to make a series of experiments upon it with the greatest care. We have, also, varied and extended these experiments in order to determine whether chloroform paralyzes the heart by a direct influence or by an indirect action through the vagus.

A number of our experiments have been made by injecting the chloroform into the jugular vein; in others it has been administered by the respiratory tract. In all cases accurate tracings have been made by means of the kymographion and the respiratory tambour.

The theory has from time to time found advocates that the vapors of chloroform may, by irritating the larynx and adjacent parts, cause arrest of the heart through a reflex inhibition. To test the possibility of this we have made a number of experiments. When the tracheal canula is tied tightly into the trachea some distance below the larynx, it is evident that the latter organ is isolated from the general respiratory tract, and that chloroform injected into it will exert only a local influence. In all the experiments which we have made in the way just indicated, the injection has been followed by an immediate and very pronounced primary fall of the pressure, followed, after a very brief interval, by a rise which usually reaches decidedly above the norm. As an example of one of these experiments, we give the following tracing.[1] (See page 192, Tracing 1.)

The primary fall of arterial pressure, which has just been spoken of, can scarcely be produced except by reflex inhibition of the heart or of the vaso-motor centres, whilst the secondary rise is probably the result of a reflex vaso-motor spasm. In order to throw light upon this question, we have made experiments by injecting chloroform into the larynx after division of the pneumogastric nerves, the trachea being ligated so as to prevent the entrance of the anæsthetic into the lungs. (See page 192, Tracing 2.)

In making practical application of the experiments just discussed, it must be noted that in no case have we succeeded in completely arresting the heart's action by injecting chloroform into the larynx, and as the chloroform was injected in liquid form, it is plain that the irritation was more intense than could be produced by the mere vapors of the anæsthetic however concentrated; therefore, while it must be considered that it is possible for a reflex inhibitory arrest of the heart to occur during the inhalation, such an accident is extremely improbable, and we consider it practically certain that a heart so arrested would, a few seconds later escaping from the inhibitory control, recommence its beat. It certainly has never been proven that chloroform can cause in the human subject permanent reflex inhibitory cardiac arrest, and as our experiments upon the dog have failed to cause such arrest, we consider it very improbable that inhibitory arrest is ever produced in man by chloroform.

The second series of our experiments were made to determine the way in which large amounts of chloroform, either thrown into the jugular vein or absorbed into the pulmonic capillaries, cause death.

We have found that it is possible for the heart and respiration to be practically simultaneously paralyzed by the anæsthetic. (See page 193, Tracing 3.)

On the other hand, the heart may be arrested during chloroformization, and the respiration continue, as is shown in the accompanying tracings. (See page 193, Tracing 4.)

We desire to call attention to the fact, that of the two tracings here inserted, one (Tracing No. 4) was made by injecting the chloroform into the jugular vein, whilst the other (Tracing No. 5) was obtained by the inhalation of chloroform. In the second experiment (inhalation) *breathing continued two minutes after the heart had ceased to act.* (See page 193, Tracing 5.)

The next series of experiments were made with

[1] The upper tracing represents the respirations as registered by a tambour, the second one the pulse waves, and the third the abscissa line and second marks.

small doses of chloroform. In a number of these cases the respiration ceased long before the heart's action, as is shown in the appended tracings, in which the heart continued to beat two minutes after the cessation of respiration. (See page 194, Tracings 6 and 7.)

The final series of experiments we made to determine whether chloroform arrests the heart by indirectly affecting the vagus or by a direct action upon it. In one experiment (Tracing No. 8) the vagi were cut before, in the other (Tracing No. 9) after the exhibition of the chloroform. It is evident that the vagal section has little or no influence upon the cardiac action of chloroform, which, therefore, acts directly upon the heart and vaso-motor system. (See Tracings 8 and 9.)

The experiments which we have given show that chloroform acts as a powerful depressant poison upon both respiration and circulation, that sometimes the influence is most felt at the heart, and death results from cardiac arrest; that in other cases the drug paralyzes primarily the respiratory centres, whilst in other instances it seems to act with equal force upon both medulla and heart. So far as practical medicine is concerned, it makes little difference whether the heart stops just before or just after respiration; so that those cases, in which cardiac and respiratory arrest are almost simultaneous, are, for the purposes of the clinician, the same as those in which heart-arrest precedes respiratory paralysis. Finally, the general results of our new experiments also coincide with our previous experience in the laboratory, and with what we believe to be the general belief of physiologists—that cardiac arrest is specially prone to occur when chloroform is administered rapidly and in a concentrated form.

The present series of experiments which we have made with chloroform are so concordant in their results with those previously obtained by other experimenters and by ourselves, that it seems to us that their results cannot be gainsaid. Therefore if a final statement should be made by Dr. Lauder Brunton and his India coadjutors that the dogs of India are killed by chloroform solely by the action upon the respiratory centre, the conclusion must be drawn that the pariah dogs of India are affected by chloroform differently from those of Europe and America. This to us seems the best explanation of the curious results obtained in India. It is possible that the climatic influence of that country may make the respiratory centres abnormally sensitive to chloroform. That the thought of the different constitutions of animals in different climates is not absurd, is shown by the fact that, some years ago—after one of us had stated before the Physiological Section of the International Medical Congress, at London, that if certain asserted results were obtained upon European dogs, said dogs must differ from those of America, and had been met with a smile of incredulity—Dr. Brown-Sequard rose and stated that he had experimented upon hundreds of dogs on both continents, and that there was a distinct difference between the animals, the vascular system of the European dogs being much more developed and operations upon them being, therefore, much more bloody than was the case with the Amer-

ican dog. Hashish causes the East Indian to run amuck and commit crime but fails so to affect the European. Whatever explanation we may accept of the different results which have been reached, we very strongly urge the consideration that these results show that the action of chloroform upon the human system is not to be estimated solely by any influence which it may have on the dogs of India. Indeed, it is possible that there may be the same difference between man in hot and cold climates as there appears to be in dogs in hot and cold climates; but we do not know of any statistics which will throw light upon such a supposition. A fact to be remembered is that though 450 pariah dogs in India have died of respiratory failure, an equal number in America have died of cardiac arrest, whilst the records of clinical medicine show that death in the human being from chloroform usually takes place either by primary arrest of the heart, or by a simultaneous arrest of the heart and the respiration, while in etherization the respiration usually ceases distinctly before the heart's beat. We do not propose in the present paper to reiterate the statistics which may be found in the text-books and recent treatises on anæsthetics, but we do desire to say emphatically that we believe the roll of deaths from chloroform would be very much larger if all the cases were reported, and that the present inequality between the anæsthetics, ether and chloroform, would be much more pronounced if an absolutely clear record could be obtained. One of us has seen, in a Philadelphia hospital, death produced by chloroform through cardiac arrest. The other has personal cognizance of two cases; but none of these instances have been reported. The surgeon who uses ether knows that he will receive no blame if a death occurs from it, and also that he has a rare case to put on record, which will give his own name a permanent place in anæsthetic literature, and consequently he naturally hastens to publish his unfortunate result; whereas the surgeon who uses chloroform knows that if death occurs from the anæsthetic, a very large proportion of the profession will condemn him either in public or secret for the use of this drug. Moreover, deaths from chloroform are only too common, so that the surgeon has nothing to gain and much to lose by publication of a chloroform death, and if possessed of the average human nature, holds his peace.

After the present paper had been sent for publication, the issue of the London *Lancet* for January 18, 1890, came to hand, and we have carefully read the report of the Hyderabad Commission. The great respect and friendship which we have for some of the members of this commission—make us loath to differ from them, but the issue between us is not simply a scientific matter, which would allow of silence, but is of such immense practical importance, involving, as it does, human life, that we feel it a duty to speak.

In the first place, we fear that the Commission's statement that their object is "to *test* the suitability and safety of chloroform as an anæsthetic," will mislead the minds of readers as to the proper scope of experiments upon animals in regard to therapeutic questions. We believe that no one will accuse us of attempting to diminish the importance of such experimentation, but we insist that the only proper objects of such experiments are to lead the way to clinical studies, and to explain clinical facts. A well-established clinical fact cannot be disproved by any amount of experiments upon animals.

We have given elaterium to dogs until it has caused death, but it has not purged. Suppose that every dog in India had had administered to it elaterium, without the production of purgation, would that prove that elaterium does not purge man? We believe that it is proven by clinical experience that, occasionally, in man chloroform does suddenly, without warning, arrest the heart's action. It seems to us scarcely possible that such conclusions as clinical reports, appear to be too definite and positive upon this point to be contradicted by experimental studies. But we believe that in verity the results of experiments with chloroform upon the lower animals are in accord with those obtained in human medicine.

In any discussion with wide differences of opinion, it is a matter of importance to determine points of agreement as well as of disagreement, and the probability of the correctness of the facts agreed upon is very great. We notice, therefore, with pleasure, that the Commission state (paragraph 18, p. 155): "The theory which has hitherto been accepted is that the danger in chloroform administration consists in the slowing or stoppage of the heart by vagus inhibition. This is now shown to be absolutely incorrect." This is in accordance with our own experimental results and conclusions, and whilst we deprecate the extreme positiveness of assertion, we think it highly improbable that chloroform ever kills man by a reflex inhibition of the heart.

In paragraph 20, p. 155, the Commission further states:

"In experiment ninety-two, repeated injections of twenty minims of chloroform were made into the jugular vein, and their effect was not to paralyze the heart, but to produce anæsthesia and a gradual fall of blood pressure, exactly as if the chloroform had been inhaled." This statement agrees with what we have already asserted in this paper. Chloroform possesses its peculiar properties by virtue of its inherent nature, and the method of administration does not altogether dominate the effects of the drug, so that conclusions can be predicted upon experiments made by injection into the jugular vein as

well as upon those in which the chloroform is administered by inhalation. The agreement of the Commission with ourselves seems, therefore, to cut off any objections to our method of experimentation, especially since in every instance we have tracings obtained by inhalation as well as by injection.

In any discussion it is very important that the essential point be closely adhered to, and not lost sight of in side issues. In the report of the Hyderabad Commission there is a great deal that is novel and of much scientific interest concerning the effects of strangling, of suffocation, of vagi-irritation, etc., upon a chloroformized animal. These are in themselves very valuable, but they are liable to obscure the one main issue—an issue which, fortunately, is tersely expressed by the Hyderabad Commission in a single line, when it says: "and, however concentrated the chloroform may be, it never causes sudden death from stoppage of the heart."

In considering this main issue, we desire, first, to call attention to the fact that the evidence of the Commission is negative, whilst our evidence is positive, and we believe it is a general law of evidence that negative testimony cannot stand against positive when the latter is trustworthy. The Commission in substance assert: We have made a large number of experiments upon Indian animals, without ever having seen the heart arrested by chloroform before the respiration—therefore, chloroform never causes death by syncope; or, to put it in another way, we have not seen a certain phenomenon, therefore that phenomenon never occurred. On the other hand, we state that we have seen this phenomenon repeatedly, and we offer in proof of our statement, not merely our own assertions, but tracings which have the same relation to physiology that the photograph has to the original transactions of life.

Further, our results in conclusion are in accord with those obtained by other observers since Glover, in 1842, first pointed out that the vapor of chloroform, when locally applied to the exposed heart, stopped its movements. The English Chloroform Commission—Gosselin, Anstie, Richardson, Ringer, and Vulpian—are among the names from whom the Hyderabad Commission appears to differ, and with whom we agree more or less closely.

Much as we differ from the Hyderabad Commission as to the conclusions which should be drawn from their experiments taken in conjunction with those of other investigators, we would dissent much more strongly from the language used by the *Lancet* itself, in its editorial of January 18th, where it says: "The practical outcome of the research would appear to be that deaths from chloroform are not inevitable. They are, therefore, preventible, and *by due care* in its administration *they may be with certainty avoided.*"

We desire most emphatically to protest against any such language being considered as justified by the work of the India Commission. If, with due care in administering chloroform, accidents may with certainty be avoided, they are, when they do occur, the result of ignorance or carelessness, and the coroner's jury, in a given case, could scarcely, under the rulings of the *Lancet*, fail to bring an accusation of manslaughter against the surgeon. We cannot help wondering if the editor of the *Lancet* appreciated the force of his own words.

According to the latest edition of Dr. Lawrence Turnbull's work on *Anæsthesia*, 375 deaths from chloroform have been recorded. If the unreported cases are borne in mind, it must be considered that at least 500 surgeons have had in their practice fatal accidents during chloroform anæsthesia; the actual number of those who have met with fatal results is probably far greater, and among these surgeons we note these names:

Professors Billroth, Dumreicher, and Jaeger, of Vienna; Sir J. Y. Simpson, Sir George H. B. McLeod, Mr. J. Farrant Fry, and Mr. Francis W. Clark, of England and Scotland; Drs. Hunter McGuire, J. H. Wellford, and Dr. Chancellor, of Virginia; Drs. W. A. Hammond, A. J. Parsons; and Professors W. W. Dawson, Kinloch, and Mussey.

Does the *Lancet* mean to charge that these accidents could have been avoided? That these men have been practically guilty of taking life through carelessness?

A NOTE ON THE EARLY DIAGNOSIS OF PERITONEAL ADHESIONS IN ABSCESS OF THE LIVER.

BY DANIEL B. D. BEAVER, M.D.,
SURGEON TO ST. JOSEPH'S HOSPITAL, READING, PA.

THE common opinion of the profession to-day is, that abscess in the liver should be evacuated as early as possible in its progress. Before the invention of the aspirator, the time fixed for surgical interference was that at which it was supposed firm inflammatory adhesion had taken place between the liver and mural peritoneum. The accepted indications of the presence of this adhesion were then, as now, subcutaneous œdema and swelling, fluctuation, and, later, inflammation of the skin. Since the introduction of the aspirator, it has become the rule to withdraw the pus with this instrument as soon as its presence has been discovered; and reports seem to show that, in a small number of cases, this early tapping has stopped suppuration and induced reparation.

Usually, however, the abscess cavity refills after aspiration, and the disease extends in one direction or another toward the surface of the liver. If it goes toward the abdominal wall, and we wait for

œdema and fluctuation, or these with redness of the skin, to appear, it may extend simultaneously in other directions, and, discharging into one of the adjacent cavities, result in long suffering or death to the patient.

Careful observation, during a number of years, of those cases of peritonitis which I had an opportunity of watching through their whole course, has convinced me that adhesion of the liver and parietal peritoneum, of sufficient firmness to prevent the flow of pus into the peritoneal sac in the evacuation of hepatic abscess through the abdominal wall, can be recognized some days before the classic indications of it appear.

Peritonitis, when due to a local cause, begins at one point at the seat of the cause, and, like inflammation in other tissues, spreads by continuity with more or less rapidity. Indeed, it probably begins in this manner in all cases; but in septic and general inflammations the disease extends so rapidly that its progress cannot be noted by the physician. But when the disease is owing to a local disorder, like abscess of one of the abdominal organs, and extends from them to the parietal peritoneum, its progress can be noted from day to day, and the more acute the symptoms the better it can be done. Accompanying the first pains of peritonitis there is tenderness on pressure over the seat of pain, usually very extreme, but perhaps over an area so small that it may be covered with the end of a finger. As the swelling of the underlying organ increases, the area of contact between it and the abdominal wall extends, and the inflammation of the parietal peritoneum, being dependent upon contact of the opposing surfaces, spreads accordingly. The portion of the peritoneum which is first inflamed becomes adherent to the opposite surface first, and as soon as the adhesion is firm enough to prevent movement and friction, the extreme pain and tenderness over its extent, be it ever so small, disappear.

If the inflammation continues and extends after a point of adhesion has been formed, the area of tenderness will move with it; and if it spreads in all directions the tender area will become ring-shaped. As the inflammation advances, the ring becomes larger, all the time preserving the excessive sensitiveness to pressure which is characteristic of inflamed peritoneum, and the central area under which adhesions have formed, and which consequently has lost its tenderness, increases in size correspondingly.

These phenomena were well exhibited in the following case of hepatic abscess:

G. M., a strong, healthy, muscular lad, sixteen years old, a moulder, complained of ill-defined pain in the pit of his stomach for three weeks, but continued at work. Then, suddenly, the pain increased so much as to compel him to go to bed. The next day I saw him, and found him in a fever, and with pain and tenderness in the epigastrium. The pain and tenderness were confined to a spot one and a half inches in diameter, of which the centre laid midway between the xiphoid cartilage and umbilicus and just to the left of the middle line. The tenderness was so intense that the least pressure beyond simple touch was unbearable, and the least movement of the body aggravated the pain most excruciatingly.

Daily examination of the abdomen revealed no change until the ninth day of his illness, and then the only change was increased resistance to pressure under the area of tenderness. By the thirteenth day the area of tenderness had increased one-half inch in diameter, and the centre was distinctly less sore to the touch than the periphery. On the fifteenth day, after a slight tympanites had disappeared, the surface over a spot two and a half to three inches in diameter appeared slightly elevated, and was firmer under pressure than the surrounding parts, and decidedly more tender on the edge than in the centre. Next day, thinking that I recognized an indistinct sense of fluctuation near the centre of the tumor, I put in an aspirator-needle slowly to a depth of two and a half inches, but failed to get pus.

On the sixteenth day the visible and palpable tumor had increased to a diameter of three and a half inches. The tumor was now again punctured with the aspirator-needle three-quarters of an inch above the seat of the previous puncture, and pus was struck at a depth of one inch. About three ounces of pus were withdrawn, and the pain and general symptoms were much ameliorated. On the eighteenth day the tumor had regained the size it had reached before the withdrawal of the three ounces of pus, the pain had returned, and the pulse and temperature risen.

I then proposed to open the abscess through the abdominal wall, but my colleague disagreed, upon the ground that as there was neither subcutaneous œdema and swelling, nor redness of the skin, there was no evidence that adhesion had taken place between the liver and the parietal peritoneum. I then related to him my observation of the beginning and spread of the pain and tenderness before he saw the case; how I had at first found both affecting a small, disk-shaped area which gradually expanded in all directions; how, as this disk grew larger, its centre became painless, and how the painless area increased with the extension of the inflammation, until the latter was represented only by a ring of tender tissues. He would not be convinced that this peculiar appearance, extension and disappearance of the pain and tenderness indicated adhesion of the liver to the abdominal wall in the painless central disk. To produce more evidence of the presence of sufficient adhesion to permit free opening through the abdominal wall, I now passed an aspirator-needle into the abscess a quarter of an inch below the puncture of the former tapping, and found pus, as before, at a depth of one inch, and then passed

the needle at a point the same distance above the old puncture with the same result.

This seemed to show, at least, that there was an abscess cavity not less than half an inch in vertical diameter, just one inch from the external surface of the abdomen, and that if there was adhesion in the middle of this line where the first tapping of pus had been made, against which there were no probabilities, it was just as likely that the adhesion extended the whole length of the cavity. It also showed that not much liver-tissue would have to be cut in making an incision into the abscess. A solution of cocaine was then injected into the upper and lower punctures, and a straight bistoury pushed one inch into the lower one and made to cut the distance of half an inch to the upper one, with very little pain to the patient. After the discharge of about seven ounces of bloody and badly smelling pus, the cavity was washed with a solution of bichloride of mercury, 1 to 4000, and a large rubber drainage-tube inserted for three inches, and covered with an antiseptic dressing. At the end of three weeks after the incision the boy was well and out of doors.

These observations may be of little interest to the consulting surgeon, who is usually called late in the course of this disease, but to the general practitioner they are of practical value, inasmuch as they, if carefully practised, enable him to fix the time when immovable adhesion between the liver and abdominal wall occurs, and hence to recognize the earliest time at which an incision can be safely made.

This method of opening an hepatic abscess before the abdominal parietes are involved possesses the disadvantage of seeming like a thrust of the knife into darkness; but if, as is presupposed, there is firm adhesion between the opposite peritoneal surfaces, it is just as simple and free from danger as the lancing of an external abscess. On the other hand, it possesses some advantages over the method of opening by dissection. It requires less skill on the part of the operator, less time, and a smaller incision; and it does not necessitate the use of ether, thus avoiding the danger of rupturing adhesions incident to the usual struggle in the early stage of etherization and the later retching and vomiting.

THE PREVENTION AND TREATMENT OF PUERPERAL FEVER.

By EDWARD P. DAVIS, M.D.,
PROFESSOR OF OBSTETRICS AND DISEASES OF CHILDREN IN THE PHILADELPHIA POLYCLINIC; VISITING OBSTETRICIAN TO THE PHILADELPHIA HOSPITAL, ETC.

Puerperal fever is an infectious wound disease produced by living ferments: these ferments are formed outside the normal body, and are by some means carried into the body from without; hence, puerperal fever is contagious. Half a century ago this statement would have been denied by obstetricians; to-day the vast majority of opinion, based on the most thorough study of the question, accepts it as true.

From what sources are these living ferments derived? Generally from animal tissues in a condition of decomposition, rarely from decayed vegetable matter. The substances causing puerperal fever are most often brought into the body through some wounded surface at the time of labor; syphilitic disease of fœtus and mother, resulting in fœtal death and abortion and cancer, may produce ferments which may be absorbed at labor, causing puerperal fever.

Gonorrhœal poison introduced into the mother's body before labor may produce living ferments which may be absorbed through a wound produced at labor, causing puerperal fever. But in the woman who comes healthy to her labor, and has puerperal fever, the disease is the result of contagion, with which she is inoculated from without. The prevention of puerperal fever consists, then, in the prevention of syphilitic and gonorrhœal infection before labor; in destroying the poisonous products of such infections, and in shielding the healthy parturient from septic poison at and after labor.

The very practical question then arises, How shall this be done? In a case where pregnancy and syphilis exist, abortion should be prevented, if possible, by constitutional treatment. The vagina should be examined for local lesions, and all ulcerating surfaces should be treated by applications of iodine and carbolic acid (tincture of iodine, 1 part; carbolic acid, dissolved in glycerin, 4 parts). The vagina should be douched twice daily with bichloride of mercury, 1 : 3000, and one or two drachms of iodoform or powdered boric acid should be deposited within the vagina, after the douche, and allowed to remain there. When the vagina is healed, one vaginal douche of bichloride, 1 : 5000, may be taken daily until labor; the administration of constitutional remedies should be continued. When pregnancy is complicated by gonorrhœa, warm vaginal douches of bichloride of mercury 1 : 3000 may be taken until the acute stage be passed; the leucorrhœa following gonorrhœa should be persistently treated by mercurial douches 1 : 5000, or creolin 30 drops or 1 drachm to the pint of warm water, twice daily; iodoform or boracic acid should be used as stated.

In the case of the healthy parturient, it is of cardinal importance that the fingers of the practitioner, and any instruments or utensils which enter the vagina, should not only be clean but antisepticized. Theoretically, perfect cleanliness is all that is needed; practically, we must take the added precaution of antisepticizing hands, instruments, and all touching the patient. For the hands, bichloride of mercury 1 : 2000 or 3000 is most efficient and conve-

nient. The hands should be scrubbed with soap and warm water, rinsed, and then scrubbed with the mercurial solution; the nails cut short, filed smooth, cleaned; rings are nuisances on the hands of surgeons and obstetricians; the cuff removed, shirt sleeve rolled up, and forearm cleansed. It is well to have a nail brush and bottle of bichloride tablets lying on the top of the articles in the obstetric bag, so that when haste is needed, a tablet may be thrown into a basin of water and the hands antisepticized at once. Rubber douche tubes and other rubber appliances may be antisepticized with bichloride solution, 1 : 1000. Metal instruments and articles may be treated by carbolic acid, 5 per cent., or creolin 1 drachm to 1 pint of water. Scalding or passing through alcohol flame is also efficient. Creolin is especially convenient because it makes a good emulsion at once with hot or cold water; carbolic acid may not dissolve properly.

When possible, the external genitals should be cleansed with soap and water and bichloride 1 : 4000. A vaginal douche of bichloride, 1 : 5000, is useful before labor. But the healthy woman, clad in clean clothing, lying upon clean bedding on a clean bed and in a clean room, is quite ready for labor, and it will be the fault of those who touch her if she has puerperal fever. While living ferments are sometimes conveyed by sewer gas, by exhalations from filth-spattered walls, and dirty hospitals, and by clothing and bedding, yet the most common manner of carrying the contagion is by hands and appliances. And dirty walls, whether roughly or smoothly finished, and dirty buildings may be so cleaned and disinfected as to be no excuse for an outbreak of puerperal fever.

Labor should, furthermore, be so conducted that the finger should enter the vagina as rarely as possible. If palpation and auscultation be practised early in labor, vaginal examinations need be few; the hand should be washed in bichloride before each examination. When the head comes upon the perineum the patient should lie on her left side, her buttocks brought to the edge of the bed, a pillow between her knees. The practitioner may conveniently sit beside the bed, facing her feet, having within reach a basin of bichloride solution, 1 : 2000, in which are bits of old clean linen or absorbent cotton. As labor progresses, the perineum should be cleansed with the bits of cotton or linen, which are then thrown into a receptacle beneath the bed. As the head emerges, the anus should be covered by cotton, and the right hand laid broadly and firmly on the perineum, the posterior commissure being received in the curve between the thumb and index finger.

In painful or precipitate labor, the left forearm may pass over the pubic joint and the head be held up beneath the pubes by the arched fingers of the left hand; when the patient threatens to expel the head suddenly, tearing the perineum, one hand may be slipped over the other, both covering the vulva, holding back the head. Cleanly practitioners keep their fingers out of the rectum, which is a sewer not concerned in normal labor. The fingers should not enter the vagina to deliver the head in normal labor, thus avoiding contagion.

The placenta should be delivered by expression, and thus entering the vagina be again avoided; one thorough vaginal douche, bichloride 1 : 5000, may be given when labor is complete; tears of the genital tract which need repair should be closed at once. Fissures and small tears may be dusted with acid salicylic 1 part, starch 5, or powdered boric acid. After instrumental delivery or version, and after the expulsion of a syphilitic or dead fœtus, vagina and uterus thould be thoroughly washed out with bichloride, 1 : 5000. From 30 to 60 grains of iodoform in suppositories may be left in the uterus in very complicated cases. A healthy woman needs but one douche after labor; the external genitals should be washed with bichloride, 1 : 5000, twice in twenty-four hours. When possible, the lochia should be received on clean old linen, and burned when removed. The following simple antiseptic napkin costs less than two cents each, if the materials are bought in quantities: a strip of picked oakum ten inches long, six wide, two thick; on each side of this two inches of cheap cotton batting, the whole enclosed in a strip of cheese cloth two feet long. This is soaked in bichloride 1 : 2000, and dried. On an average, six are used for each of the first three days; four daily afterward; they should be removed when soaked through, and burned.

Puerperal fever, practically, is of two kinds: one in which poison is directly absorbed by the uterine circulation at labor; the other, in which poison is absorbed through the lymphatics from the vagina. The latter is the most common; is marked by swelling, infiltration, ulceration of the genital tract, with absorption and pyæmia. Its symptoms are fever, pain in the abdomen, foul lochia, high pulse. It is to be treated by thorough examination of the vagina, touching ulcers with iodine and carbolic acid; by four vaginal injections in twenty-four hours, of bichloride 1 : 5000, or creolin 30 drops to the pint, after the douche, iodoform or boric acid to be freely sprinkled in the vagina. Abdominal pain is best treated by turpentine stupes, followed by dry heat. Intestinal elimination should be prompt and thorough; 5 grains of calomel with soda may be given at night and a saline in the morning, or concentrated saline solutions in small repeated doses. Food should be liquid, easily digested and abundant; alcohol may be freely given. Quinine, 5 grains three times daily,

or sodium salicylate, 20 grains three times daily, is useful. Antipyrin in 5 grain doses repeated two or three times at night will relieve restlessness and pain. Large doses of antipyretic drugs and of opium are to be avoided.

Should the symptoms persist after such treatment for forty-eight hours, the uterine cavity must be disinfected. If the uterus is relaxed, the cervix torn, the os open, an ordinary douche tube may be attached to the fountain syringe, and after a vaginal douche a quart of creolin 1 drachm to the pint, carbolic acid 2 per cent., thymol 1 : 1000, boric acid saturated solution, alcohol and water 1 : 3, or bichloride 1 : 8000 or 10,000, at a temperature of 100° to 110° F., should be allowed to pass gently into the uterus, the return flow being carefully observed ; the fountain syringe should be three feet above the patient's bed. If the os is not widely open, an intra-uterine catheter should be used, or a large vesical catheter, while the os be held partly open by dressing forceps. These injections may be made twice daily, vaginal douches continuing. If the lochia continue foul after intra-uterine douches, the use of a large bladed dull curette is indicated, to remove infected decidua accompanied by the douche ; this should rarely be repeated if thoroughly done at first, and iodoform in suppositories may be placed in the uterus afterward. By these means the genital tract may be thoroughly disinfected, and after the faithful use of intra-uterine douches for a few days their continuance is of doubtful utility. Vaginal douches should continue, and the treatment be directed to the pyæmia or septicæmia from which the patient suffers.

Pyæmic abscesses, when external, should be opened, drained, and disinfected. For the constitutional debility and fever which accompany both septicæmia and pyæmia, alcohol should be pushed to the verge of intoxication. For fever, antipyretics should rarely be given ; temperature should be reduced by sponging with cold or hot water, by packing in cold or hot wet sheets, occasionally by the graduated bath. A reduction of fever by these means will be accompanied by a return of appetite ; milk, eggs, soups, beef-essence, scraped beef, with the best wines and brandies, should then be taken. The only antiseptic which can be safely used internally is alcohol, and that should be pushed ; from one to two pints of brandy in twenty-four hours, with wine in abundance, has been given with good results. When vomiting occurs, cocaine may be used to advantage. For septic diarrhœa, bismuth salicylate may be freely given. The best brandy to be had in America is Naglee's California brandy ; if this cannot be procured, old whiskey is more apt to be pure than so-called French brandies. Alcohol and water will occasionally be retained when no other form of alcohol can be taken. The continued administration of quinine, 5 grains three times daily, or sodium salicylate 10 grains three times daily, may be continued *if the stomach be not disturbed by them :* if this happens, they should at once be abandoned, and alcohol and food made the principal treatment. Puerperal peritonitis may be treated by incision, introducing a tube among the intestines, and flushing the abdomen with hot water (110° F.). Ice, applied to the abdomen or to the head, has been a useful adjuvant. Faithfully treated upon the principles stated, seventy per cent. of cases of puerperal fever have recovered in the practice of those who have most thoroughly studied the subject.

THE TREATMENT OF HYSTERICAL APHONIA, ASSOCIATED WITH HYPERTROPHIC RHINITIS, BY CAUTERIZATION OF THE TURBINATED BODIES.

By W. E. CASSELBERRY, M.D.,

PROFESSOR OF THERAPEUTICS AND MATERIA MEDICA, AND OF LARYNGOLOGY AND RHINOLOGY IN THE CHICAGO MEDICAL COLLEGE ; LARYNGOLOGIST TO THE SOUTH SIDE FREE DISPENSARY OF CHICAGO, ETC.

Pathological reflexes which have been described as emanating from the nose are so numerous and diverse that, unless one be intimately familiar with the possibilities, a sense of scepticism might arise. The term "reflex" is, doubtless, often misapplied, yet it has a definite significance ; sneezing, for example, is a physiological reflex designed to rid the upper respiratory tract of irritating particles which may have gained access thereto. The sensory impression in the nose travels *via* the nasal branches of the ophthalmic division of the fifth nerve and the nasal branches of Meckel's ganglion in connection with the superior maxillary division of the fifth nerve to the medulla. It is there reflected to the respiratory, pneumogastric, glosso-pharyngeal, and other centres, whence efferent impulses result in the deep inspiration, the forced expiration, and the coincident spasm of the pharyngeal muscles termed a sneeze. With a violent sneeze is often combined the element of cough, in which case contraction of the laryngeal muscles is excited in the same manner by nasal irritation.

"Nasal cough," as a pathological reflex, has been established by John N. Mackenzie,[1] Wilhelm Hack,[2] and others.

Cough was instantaneously excited whenever I passed a cotton probang into the left middle meatus, in the case of a child who suffered from polypi of

1 Nasal cough, etc., American Journal of the Medical Sciences, July, 1883. Cases of Reflex Cough due to Nasal Polypi, Transactions of the Medical and Chirurgical Faculty of Maryland, 1884.

2 Ueber eine Operative Radical Behandlung von Migräne, Asthma, Heufieber, etc. Wiesbaden, verlag von J. F. Bergman, 1884.

that nostril, and this phenomenon was repeated many times in the course of treatment. Otherwise cough was not one of the symptoms, and no cough could be excited by the same manipulation in the right nasal fossa, which was nearly normal. Evidently the polypi maintained a state of superexcitation in the surrounding area, to which only the additional irritation of the cotton was necessary to excite reflex cough.

The terms "neurosis" and "nervous habit" are also often of indefinite significance, yet the existence of a neurotic temperament is conceded by everyone. Neurotic individuals are more susceptible to some or all forms of nervous impressions. Had the child above mentioned been of more pronounced neurotic temperament, it is probable that the polypi alone would have sufficed to produce cough, as in Dr. Mackenzie's cases.

With another child suffering from atrophic rhinitis, the passage of a cotton probang into either middle meatus invariably provoked cough; and in still another patient affected with hypertrophic rhinitis and septal deformity, in whom cough was a prominent symptom, manipulation anywhere in the nose excited such paroxysms of cough as seriously to interfere with treatment.

From these observations it is apparent that the "sensitive areas" are not circumscribed, but cover in some degree all portions of the nasal fossa, the anterior parts being quite as sensitive in this respect as the posterior parts.

Spasm of the glottis may ensue by reflection of irritation from the naso-pharynx, as in a young woman who had suffered for years from typical attacks of laryngeal spasm, and in whom examination disclosed a mass of adenoid vegetations. Direct irritation of this hypertrophy accidentally made by a strong upward spray, and again purposely by means of a probe, resulted in attacks characterized by prolonged, shrill, whistling inspiration and cyanosis, the second one of which lasted for a minute—suggesting preparations for laryngotomy, and was so alarming that I willingly refrained from further experimentation in this direction. Removal of the adenoid hypertrophy—not quite complete because of the brevity of her stay in town—ameliorated the condition from several attacks daily to a mild one every week or two.

That the irritation of adenoid hypertrophy in the naso-pharynx may excite, reflexly, a much more widely distributed spasmodic state than that of the larynx alone was demonstrated by a child, sent me by Dr. E. J. Doering, who had suffered from violent and rapidly recurrent asthmatic seizures, which resisted change of climate and all forms of treatment until a mass of adenoid vegetations was removed. Only four comparatively mild attacks occurred during the following year, and these can be accounted for by remaining remnants of the adenoid growths, in connection with a disposition to "catch cold" and a susceptibility to bronchitis.

Nasal irritation acting reflexly in conjunction with weak and excitable nerve-centres, is further cited among the causes of migraine, supra-orbital neuralgia, otalgia, chorea, epilepsy, etc.; while, in turn, muscular action in the larynx may be excited reflexly by distant irritation elsewhere than in the nose, of which "aural cough," caused by irritation in the external auditory canal of the auricular branch of the pneumogastric nerve, is a familiar example.

I have cited these illustrations as a reminder of the established fact that nasal irritation is capable, under certain conditions, of exciting muscular action in the larynx. *It is now proposed to study circumstances from which it would seem that this rule can be worked the other way, and the correlation between the nerves of these organs utilized, therapeutically, to correct functional laryngeal paresis by artificial irritation applied to the nasal tissues.*

Sister C., a teacher in a Roman Catholic academy, suffering from "hysterical aphonia," was referred to me by Dr. W. E. Quine. She had had a previous attack two or three years before. Treatment then was of no avail, phonation having commenced finally, unassisted, as suddenly as it had disappeared. The last seizure commenced suddenly, was of some weeks' duration, and had resisted many forms of treatment. She was very anæmic and generally debilitated, but seemingly devoid of serious organic disease or pronounced hysterical manifestations. The inferior turbinate bodies were much hypertrophied, in consequence of which one or the other nostril was constantly occluded. Laryngoscopic examination disclosed that paretic state of the vocal cords which, in the absence of other cause, is commonly attributed to hysteria. The bands presented a relaxed, flabby aspect, and upon attempted phonation they would scarcely meet in the median line, then instantly separate, leaving an elliptical space or a slit between them.

The usual remedial measures—intra-laryngeal faradization, alkaline and astringent sprays, iron and strychnine internally—employed during three weeks, proved of no avail. Then, in view of possible association with the hypertrophic rhinitis, electro-cauterization of its inferior turbinals was commenced. During the two days following the first linear burn, about four centimetres in length and in depth to the bone, she spoke a few words aloud. After its second cauterization the voice returned permanently, increasing somewhat in strength as treatment progressed.

In another case, Mrs. G., aged forty years, aphonia supervened upon a severe "cold" six weeks before There were signs of infiltration in the right infro-clavicular region, but the bacillus tuberculosis was not discovered. Pulmonary pains, harassing cough, profuse expectoration, sore throat, and gastro-

intestinal derangement had been of frequent occurrence for years. She was of a highly nervous temperament.

On attempted phonation, the cord from the anterior commissure to the vocal processes would meet, but again instantly separate, leaving, in this position, a narrow elliptical slit, while a triangular space always remained between the segments of the cord, posterior to the vocal processes. The paresis was associated with only slight congestion of the larynx. She had hypertrophic rhinitis, follicular pharyngitis, and chronic tonsillitis. Constitutional treatment, intra-laryngeal faradization, alkaline and astringent sprays, and cauterization of the enlarged pharyngeal follicles, during three weeks, failed to improve the voice. The enlarged turbinated bodies seemed to occasion no inconvenience, but I now subjected them to electro-cauterization, as in the previous case, and with precisely the same results. Within two days she spoke some words aloud, and after the second treatment she permanently regained her voice. Now, after fifteen weeks, the vocal bands still appear relaxed, and the triangular space, though less, is yet present, notwithstanding which she speaks in a fair tone of voice.

The muscles involved in each of these cases were chiefly the adductors, thyro-arytenoidei interni, crico-arytenoidei laterales, and the inter-arytenoideus, the latter especially in the case of Mrs. G., as was shown by the triangular space mentioned. These muscles are supplied by the recurrent laryngeal branch of the pneumogastric nerve, which also receives fibres from the spinal-accessory. The thyro-arytenoidei interni act at the same time as tensors, and, further, it is not improbable that the abductors, crico-arytenoidei postici, supplied by the same nerve, were sufficiently involved to affect their tensor function. Likewise the especial tensors—the crico-thyroidei, supplied by the superior laryngeal branch of the pneumogastric—were possibly involved.

Few cases described as "hysterical aphonia" belong strictly to that category. Gerhardt, cited by Sir Morell Mackenzie, thinks some of them belong to the class of "reflex paralyses," and I am informed that he has reported a case cured by cauterization of the inferior turbinated bodies. More often it is the simply anæmic and those debilitated by phthisis, independently of laryngeal tuberculosis, who suffer from functional aphonia. It follows inflammation and laryngeal rheumatism from "cold," in which case the congestion disappears, but the aphonia remains indefinitely.

The defect may lie in a perverted distribution, or in an inadequate supply of nerve-force to the parts, or there may exist a state of inherent muscular weakness requiring increased nerve-force for action, which, in debilitated subjects, is not forthcoming. Whichever it may be, if we can stimulate energetically and somewhat continuously the branches of the pneumogastric nerve which supply the larynx, it would seem possible to restore their flagging energies or to redirect the perverted nerve-force into its proper channels.

We have seen that the nerve-filaments of the nares are in intimate reflex communication with those of the larynx, and that spasmodic action in the normal larynx can be excited by pathological irritation in the nose and naso-pharynx. Why, then, may not the larynx, in a state of paresis, have its nervous supply reflexly energized to the normal standard by cautery irritation to the nerve filaments supplying the inferior turbinals of the nose?

The excitation passes to the medulla *via* the nasal nerve, a branch of the ophthalmic division of the fifth, which supplies the anterior end of the inferior turbinate body, and *via* the nasal branch of the anterior palatine which supplies the rest of the turbinal, descending from Meckel's ganglion which is connected by its sensory root with the superior maxillary division of the fifth nerve. Reaching the medulla, it is reflected to the pneumogastric and spinal accessory centres, to be transmitted thence to the laryngeal muscles. This is submitted as seemingly the most reasonable explanation of the results obtained in the cases cited.

What causal relationship, if any, existed between the hypertrophy of the inferior turbinate and the laryngeal paresis is not easy to determine. The hypothesis advanced by Woakes,[1] in explanation of paresis of the laryngeal adductors, and of the velum palati in association with ethmoiditis, that irritative impulses pass from the nose *via* the sympathetic system to the superior cervical ganglion, thence as vaso-dilator waves to the arterioles of the parts, occasioning paresis through vascular engorgement, is not tenable in these cases, because it does not explain the immediate improvement of the voice upon the additional irritation of the cautery to the turbinals.

Circumstances in each case preclude the supposition of action through mere mental impression: the intra-laryngeal faradization and cauterization of enlarged pharyngeal follicles being equally impressive and arousing in their nature, and, to the mind of a patient, more in harmony with the object in view than treatment directed to the nose. Nor would one anticipate the same results from cauterization at random elsewhere on the body, for it is demonstrated that a special reflex relationship exists between the sensory filaments of the nares and the motor nerves of the larynx; and, finally, with the physiological action of the remedy thus known, so to speak, one is assisted in distinguishing between the *propter hoc* and merely the *post hoc*.

VALUE OF THE GENU-PECTORAL POSITION IN GYNECOLOGICAL TREATMENT.

BY J. N. MARTIN, M.D.,
OF ANN ARBOR, MICHIGAN.

I AM well aware that the genu-pectoral position is frequently mentioned, but I believe its full value is not generally appreciated. I have, for several months past, utilized this position much oftener than formerly, both in hospital and in private practice, and am convinced that in certain pelvic disorders it is of great value and will obviate the need for more dangerous procedures.

Among the indications for this position are posterior displacements, with or without adhesions, prolapse, enlargements of the uterus from any cause, and pelvic inflammations. In many cases of anterior displacements patients are materially relieved by it. If practised correctly, we simply call into use gravitation, or atmospheric pressure by loosening all the bands about the abdomen, in order that the abdominal viscera may drop down while the patient is in the position, thus forming a partial vacuum between the abdominal and pelvic viscera; and now, if the perineum is retracted, the atmospheric pressure through the vagina forces the uterus and appendages down toward the abdominal viscera. By the action of gravitation, blood-pressure is much diminished in the pelvis; in other words, the congestion is greatly relieved. If the uterus is displaced posteriorly, all pressure opposing replacement is removed, and, if there are no adhesions, it will, as a rule, return in a few minutes nearly or quite to its normal position, without the use of repositors or sounds; if it does not, after the patient has been in this position a few minutes, gentle pressure from behind will replace the uterus without pain to the patient. The patient should be required to repeat this several times daily, and after a few days she will be prepared for a pessary. If there are adhesions binding the uterus down, order douches of hot water daily until sensitiveness is diminished, then advise the knee-chest position several times a day, with or without deep respirations, *pro re nata*—the frequency and duration of the posture being governed by the amount of pain produced. Later, gentle pressure from behind may be added to the atmospheric pressure. This treatment has a marked resolvent effect upon the adhesions, and, when added to the usual treatment, materially hastens the recovery.

I have treated several bad cases of posterior adhesions during the past year, with most excellent results, and among them one who was advised by a prominent Chicago gynecologist to have the adhesions broken up through abdominal section. To-day she calls herself well.

Patients properly instructed can do much to aid the physician in his efforts. I recall two cases who could not, in the beginning of the treatment, remain long in this position without severe pain, but by regulating carefully the treatment, they were greatly improved. If the uterus is retroverted and gravid, with no tendency to right itself, the dangers of producing abortion are greatly diminished if the patient remains in this position a few minutes before an attempt is made at replacement.

Patients who suffer, soon after getting up from confinement, from dragging weight and pain in the pelvis, back, and sides, are much relieved by taking this position three or four times a day, and especially for a few minutes before retiring; and I believe this assists much in preventing subinvolution and displacements, which are so apt to occur at this time.

For women who work hard, and are on their feet all day, and who, when night comes, complain of fulness and pressure in the pelvis, with dragging pains in the back, etc., I know of no simple means that will give so much relief as the knee-chest position, with a few deep inspirations, before retiring. By so doing, if there is a tendency to prolapse or congestion of the uterus, or too much traction on the ligaments, the uterus is usually replaced, circulation is improved, and the patient rests better as a result.

Sims's position, I admit, is a fair substitute in some conditions, but is not so generally useful, and its favorable results are not so marked. I do not claim, by any means, that this position is a panacea for diseases of women; but it is a valuable adjunct in treating all chronic inflammations of the pelvic viscera and most displacements, and, while I am aware that it may be resorted to too vigorously, especially when there are adhesions, I feel sure that if it were utilized more often, patients would be saved much pain, and recovery would be hastened in a majority of cases. But this adjunct, as well as many others, in order to do good, must be directed by one who understands the physiology and pathology of the pelvic organs.

CLINICAL MEMORANDA.

ORTHOPÆDIC.

Torticollis as a Cause of Scoliosis.—The great importance given of late to rotation of the bodies of the vertebræ, paralysis and hypertrophy of the thoracic and spinal muscles, faulty positions, contracted inflammatory products intra- or extra-thoracic, inequality of the lower extremities, etc., has led many to neglect or entirely overlook torticollis as a direct factor in the etiology of scoliosis.

The study recently of two interesting cases in which wry-neck was the primary and only cause of the lateral curvature has led me to record them.

CASE I.—C. M., aged six years, blonde female child of healthy parentage and with good previous history, came under my care in 1886, suffering with marked

lateral curvature of the spine. The mother stated that the child was delivered with instruments, and had from birth a wry-neck, the right sterno-mastoid being contracted and the chin drawn to the left side. This appeared to diminish somewhat, but when about five years of age the curvature of the spine was observed. On examination, there was found a marked cervical curve to the left, another in the dorsal region to the right, and a slight curve in the lumbar region. The child was fairly developed for her age, and the lower extremities were, on measurement, exactly equal in length. The head could not be brought beyond the median line. Tenotomy was proposed, but for the time rejected, and a lateral curvature brace applied, with double-bar suspension, massage, and the use of a hair pillow under the right side. The case did not progress satisfactorily, and the year following a tenotomy of the sterno-mastoid was performed, after which the head assumed a natural position and the deformity diminished under appropriate treatment.

CASE II.—T. B., aged fifteen years, residing in Philadelphia, consulted me recently for a marked curvature of the vertebral column. The maternal father and brother had died of phthisis, but otherwise no hereditary disease or history of deformity could be elicited. Since birth he has always had wry-neck, and there has always been some curvature of the spine and elevation of the right shoulder. The patient is a well-developed youth, whose general health has always been excellent. Two years ago, whilst walking, he was seized with a severe pain in the right shoulder, which continued and led him to seek medical advice. On examination, there was found a marked cervical curve to the left and a compensatory dorsal curve to the right, with elevation of the right shoulder. The head was slightly flexed and drawn to the left side. The lower extremities were of exactly the same length, and there was no tilting of the pelvis.

The exact process by which a cervical curvature from wry-neck induces a lateral curvature of the entire column may be interesting. The deviation of the head to one side and the flexion of the chin upon the thorax by the unilateral contraction induce a bowing of the cervical vertebræ to that side and rotation of the bodies upon one another. There is at once produced a characteristic alteration in the outline of the neck, the graceful double curve becomes flattened, the neck shortened, and the shoulder less prominent on the one side, while the curved line becomes more pronounced, the neck longer, and the shoulder more prominent on the other side.

The natural balance of the column being disturbed, nature endeavors by a compensatory dorsal curve to restore the equilibrium. This induces a rotation of the bodies of the dorsal vertebræ with all its attendant deforming features: the flattening and twisting of the scapula on one side, the deviation of the spinous processes in a serpentine direction from the median line, and the elevation and projection backward of the scapula on the other side. With the development of a third or lumbar curve the crest of the hip becomes obliterated on one side, the waist line deepens, the hip becomes prominent on the other side, and the lateral outlines become everywhere less symmetrical.

The contraction continuing, anatomical changes are produced which not only tend to fix the vertebræ in their deformed relations, but also to exaggerate the abnormal curves. These changes are chiefly atrophy of the bones and intervertebral cartilages on the concave side of the curve, with shortening of the ligaments and muscles, and hypertrophy of the bone and cartilage, with elongation of the ligaments and thickening of the muscles on the other side.

The diagnosis of wry-neck as a cause of lateral curvature, while extremely easy when seen early, becomes exceedingly difficult when the primary, secondary, and even a tertiary curve have developed and the position of the head from the existence of these curves has lost some of its most distinctive features. With the development of the spinal curves, the added prominence of the hip, the growing out of the opposite shoulder, and the distortion of the thoracic wall, in the absence of a direct previous history, the diagnosis becomes uncertain and the treatment, if empirical, becomes unsatisfactory.

In the second case there was no history of direct injury at the time or following delivery, but there was a history of torticollis. With this added to the entire absence of other causes, especially inequality of the lower limbs, the wry-neck as the primary cause of the marked primary cervical and secondary dorsal curve could not be mistaken.

In this case the head was freely movable, but rested in natural repose with the chin to the left side. The patient has a well-developed muscular system, and has responded so well to the usual methods that an attempt will be made to correct the deformity without resorting to tenotomy.

JAMES K. YOUNG, M.D.,
Instructor in Orthopædic Surgery in the University of Pennsylvania

MEDICAL PROGRESS.

Aristol, a Substitute for Iodoform.—DR EICHHOFF, of Eberfeld, writes quite enthusiastically of *aristol*, a compound of iodine and thymol, recently manufactured by Bayer & Co. (*Monatshefte f. praktische Dermatologie*, January 15, 1890). Eichhoff believes that the new drug will supplant iodoform, not only in dermatological practice, but in other conditions where iodoform has heretofore been used, having the therapeutic properties of the latter drug without its disagreeable odor or toxic effects. The author has employed aristol only in diseases of the skin, including varicose ulcers, eczema, lupus, psoriasis, etc., and, after reporting his cases in detail, concludes:

1. That aristol is in all cases a harmless drug.
2. That it is a powerful parasiticide.
3. That in the ulcerations of tertiary syphilis curative results are obtained more rapidly than with any other drug.
4. It is the most useful of all applications in the treatment of lupus.
5. In the treatment of psoriasis it does not act quite as rapidly as chrysarobin or pyrogallic acid.

The aristol was in most cases applied as a ten per cent. ointment in vaseline.

Glycerite of Belladonna.—MR. A. W. GERRARD highly recommends the glycerite of belladonna for checking the pain of poisoned wounds, boils, and abscesses. Applied to the breast it suppresses the secretion of milk

with far more certainty than belladonna plaster. It should be made according to the following formula:

R.—Alcohol. ext. of belladonna, Alcohol } of each 1 part.
Glycerin . . . . . 2 parts.

Mix the extract and alcohol before adding the glycerin.

A formula that will serve the same purpose, and which is more elegant, is as follows:

R.—Atropine sulphate . . . 4 grains.
Camphor water . . . 2 fluidrachms.
Glycerin . . . . . 6 " —M.

—*Illustrated Medical News*, January 25, 1890.

Formula for Sulphonal.—MOSSÉ recommends the administration of sulphonal, particularly where sleeplessness exists from bronchitis, in the following manner:

R.—Sulphonal . . . . . 10 grains.
Rum . . . . . 1 ounce.
Syrup of acacia . . . . 1 "
Water . . . . . 2 ounces.—M.

Treatment of Eczema.—After considering the necessary means for the internal treatment of eczema, VEIEL recommends the simultaneous administration of arsenic internally along with local treatment. If chlorosis exists, he prescribes iron, to be given an hour before meals; or, if the eczema is dependent on scrofulosis in children, he recommends cod-liver oil and a thorough regulation of the diet. In pruritus he employs chloral internally combined with bromide of potassium. To allay the sensation of itching which is apt to accompany acute eczema associated with much secretion, he recommends the formula originally devised by Unna, consisting of:

R.—Oxide of zinc . . . . 15 parts.
Gelatin and glycerin, of each . 25 "
Distilled water . . . 45 " —M.

The skin should be washed sufficiently frequently to remove the scabs and keep it clean. Where the eczema is exceedingly moist, the parts may be bathed very often to remove the scabs. Where the eczema is general and the itching is intolerable, a powder of starch containing two per cent. of camphor may be added, and if this does not succeed, borax, salicylic acid, alum, glycerin, and distilled water may be employed, the borax and distilled water being in the proportion of two per cent.

Caries of the Teeth.—According to MILLER, the following formula is one which will be useful in the prevention of dental caries. It consists of:

R.—Thymol . . . . . 4 grains.
Benzoic acid . . . . 45 "
Tincture of eucalyptus . . ½ ounce.
Alcohol . . . . . 3 ounces.
Essence of peppermint . . 10 drops.—M.

or,

R.—Thymol . . . . . 3 grains.
Benzoic acid . . . . 45 "
Tincture of eucalyptus . . ½ ounce.
Chloride of mercury . . 10 grains.
Essence of peppermint . . 10 drops.—M.

For these to prove efficacious, it is necessary that the mouth should be thoroughly rinsed, and that the liquid should find entrance into the spaces between the cheek and the gums, and also the spaces between the teeth. Particularly is this the case after animal foods have been taken.

Tamponing the Uterus for Post-partum Hæmorrhage.—DÜHRSSEN'S method of checking post-partum hæmorrhage by plugging the uterus with iodoform gauze, is apparently growing so steadily in favor that the following description of the *technique* (*Lancet*, January 25, 1890), as carried out by Dührssen himself, should be read with interest.

If the uterus does not contract under friction and ergotine injection, the patient is at once placed in the lithotomy position, the external genitals are thoroughly cleansed with soap, and three per cent. carbolic solution; the catheter is passed, the vagina disinfected with at least one quart of three per cent. carbolic solution, and the uterus is then irrigated with the same, or, if the patient is very anæmic, with a solution of salicylic acid (3 per 1000) or with simple boiled water. If bleeding continues, the uterus is explored with two fingers, to make sure that nothing is left behind. The cervix is then seized with one or two vulsellæ and drawn down to the vulva; or the plugging may be done through a duck-bill speculum, or even with two fingers of the left hand used as a duck-bill speculum. The end of the gauze bandage is then seized with long speculum forceps, the left hand grasps the fundus uteri, and the end of the bandage is carried up to the fundus; the bandage is then packed into the uterus bit by bit. The vagina is next packed in a similar manner, or, if there is cervical bleeding, with tampons of cotton-wool. Care must be taken that the packing material is not soiled on its passage into the uterus, for in the only fatal case of sepsis recorded the gauze bandage had been allowed to trail on the floor. This, however, was not in Dr. Dührssen's practice. In severe cases he adopts plugging in the first instance as the safest means. In only one case was hæmorrhage immediately fatal, four other cases died of anæmia after arrest of the bleeding, one of these of œdema of the lungs, which was present before the uterus was plugged. The other case was that of sepsis mentioned above, in which the gauze had been allowed to trail on the floor.

The table accompanying Dührssen's paper (Volkmann's *Sammlung klinische Vorträge*, No. 347) includes many cases of severe hæmorrhage. While it is difficult to estimate the gravity of each case from a description, it would seem that in plugging the uterus and vagina we have a valuable addition to our resources in the treatment of post-partum hæmorrhage, and one that is not prone to substitute one great peril for another; indeed, it is easy to understand that, when properly performed, sepsis is rather avoided than encouraged, the gauze acting as an efficient drain.

Nephro-lithotomy.—In a valuable paper upon renal calculus, MR. W. H. A. JACOBSON (*British Medical Journal*, January 18, 1890) submits the following practical points to be observed in the performance of nephro-lithotomy:

1. Count the ribs. That this is not an unimportant

detail is proved by the fact that Dumreicher, of Vienna, accidentally opened the pleural cavity in an attempt to remove a pyelo-nephritic calculous kidney. *Post-mortem*, the last rib was found to be rudimentary, and the pleura projected below the lower edge of the eleventh rib.

2. Make a sufficiently free incision, especially in a stout patient, and a deep loin. Additional room may be gained by converting the usual lumbar incision into a T-shaped one, or by making use of König's incision, in which the muscles are cut through as far as the rectus, and the peritoneum pushed forward. A small stone in a kidney will always be liable to be overlooked, but a surgeon does not give a patient or himself a fair chance who is content with exposing the kidney through a limited incision, and then trusting to punctures with a needle.

3. Pack the colon out of the way with sponges, as it is often troublesomely distended with flatus in these cases.

4. If the stone cannot be felt either in the pelvis or after palpation of the posteror and anterior surfaces of the kidney, this should be drawn up and out of the wound as far as possible, and again examined, a careful watch being kept upon the pulse.

5. In puncturing the kidney, try, as far as possible, to open the calyces systematically.

6. If palpation and acupuncture fail to reveal a stone, the kidney should be carefully opened and sounded.

7. Hæmorrhage from an incision into the kidney is certainly arrested by firm, careful plugging with strips of sal alembroth gauze. On the five occasions on which Mr. Jacobson has adopted this plan, he has removed the strips the next day with the aid of a few minutes' anæsthesia, gas sufficing for this. It is said that the plugging may cause vomiting, but this did not occur in any of his cases. Care must be taken that the plugging is thoroughly done. If inadequate, it will have to be repeated in a few hours—perhaps more than once—thus leading to exhaustion, and setting up cellulitis, which may of itself be fatal owing to the important relations of the kidney.

Treatment of Pregnancy during Phthisis.—At a recent meeting of the Obstetrical Society of London (*British Medical Journal*, January 18, 1890) DR. WILLIAM DUNCAN reported a case of pregnancy during phthisis, in whom he had induced premature labor. In the course of his remarks he stated his belief that during pregnancy phthisis was not retarded, as was formerly believed, but hastened. This was especially the case in women between twenty and thirty years of age. When phthisis was progressive, in early pregnancy, there could, in his mind, be no question that the proper course to pursue, after careful consideration of the case in consultation, was to empty the uterus of its contents. Even when the phthisis was stationary, it was safer to empty the uterus at once than to let the pregnancy proceed to term. When the patient was seen for the first time late in pregnancy, the child being viable, the case was different. He would be guided, under these circumstances, by the condition of the lungs. If phthisis were stationary, though well marked, he would wait until full term had nearly arrived, and then, in order to save the patient all suffering and the strain on her system consequent on natural delivery, he would dilate the cervix with graduated bougies, followed by the hydrostatic dilators, until it was sufficiently expanded to permit of delivery by the forceps or version, as the case indicated. Full antiseptic precautions would be taken. If, however, the pulmonary disease were markedly advancing, the interests of the mother and child would be best served by effecting delivery in the same manner without delay, instead of waiting until the full term had been reached.

In discussing this paper, DR. PLAYFAIR thought that the treatment advocated was unjustifiable, and liable to serious abuse in early phthisis. In advanced phthisis the matter was different; but even then, there were not sufficient grounds or believing that premature labor would materially change the course of the disease. On the whole, he believed that Dr. Duncan's case was a dangerous precedent. The other members of the society, without exception, condemned the course of treatment advised and pursued by Dr. Duncan.

Menthol in Diseases of the Throat and Nose.—MR. J. LENNOX BROWNE says that the vapor of menthol checks in a manner hardly less than marvellous, acute colds in the head, and is also to be recommended with a certainty of success, if used on its first onset, in arresting epidemic influenza, even in cases in which the nasal symptoms commonly associated with the word influenza are not manifested.

Menthol exerts its action in the following manner:

1. It stimulates to contraction the capillary blood-vessels of the passages of the nose and throat, always dilated in the early stages of head cold and of influenza.

2. It arrests sneezing and rhinal flow.

3. It relieves, and indeed dissipates, pain and fulness of the head by its analgesic properties, so well known when applied externally to the brow in cases of *tic douloureux*.

4. It is powerfully germicide and antiseptic. It thus kills the microbe of infection, and prevents its dissemination.

The remedy may be employed by means of a general impregnation of its vapor through a room or house, or locally to the nostrils and air passages: for both of which purposes there are several methods:

(*a*) A ten to twenty per cent. solution of menthol in almond oil, in liquid vaseline, or in one of the many other odorless paraffin compounds, can be sprayed into the nose or throat, or about a room.

(*b*) By placing twenty or thirty grains in an apparatus specially designed by Rosenberg for administering the drug in cases of laryngeal phthisis by inhalation, in the form of vapor mingled with steam.

(*c*) By a simple arrangement of placing a saucer of water containing a similar quantity of the crystals over a gas burner in the hall, by means of which the whole house is kept constantly permeated with the drug.

(*d*) But by far the most convenient method for personal use is to carry always the ingenious pocket menthol inhaler, known as Cushman's, which should be used not only on the first approach of an attack, but three or four times a day in "cold-catching" weather by those subject to coryza.

The instrument consists of a glass cylinder four inches in length, half an inch in diameter, and open at both ends. The tube contains crystals of menthol closely

packed and prevented from escape by perforated zinc and cork. The opening at one end is twice the size of the other, the larger being intended for inhalation by the mouth, the smaller for the nostril. The latter is the method which the author, by preference, recommends. It is not to be simply smelt, but well sniffed or inhaled, so as to cause some tingling or smarting, a sensation which is quickly followed by that of coolness, and openness of the previously "stuffed" and heated nostril. By its use, when the nasal discharge is excessive, it is checked; when deficient and thickened, as in hypertrophic rhinitis, its healthy character is restored; and when arrested, inspissated and malodorous, as in atrophic rhinitis, fluidity is promoted and the foul smell corrected.—*Boston Medical and Surgical Journal*, January 30, 1890.

[Our own experience is that ten or twenty per cent. solutions of menthol in oil cannot be sprayed into the nasal cavities, unless there is advanced atrophic rhinitis, without causing considerable pain and discomfort to the patient.—ED.]

Preparation of Ergotin for Hypodermic Injection.—According to MR. A. W. GERRARD, the officinal ergotin (B. P.) is merely a purified extract of ergot, although it well represents the activities of the crude drug. The chief objection to its hypodermic use is the irritation it causes, which, however deeply it may be injected into the muscles, is at times very great. Gerrard finds that ergotin is very acid in reaction and full of inert matter, and that if these are eliminated great improvement results. For this purpose one part of ergotin may be treated with four parts of absolute alcohol, stirring well during the addition. Then pour off the alcoholic solution and evaporate over a water bath to a soft residue. This treatment removes inorganic salts and a mucus-like substance. The acid still remains, and should be carefully neutralized with a solution of ammonium. Ergotin thus treated is highly active, and rarely causes severe irritation after injection. To prepare a solution that keeps well for hypodermic use, rub up one part of ergotin with one of glycerin and two of water.—*Illustrated Medical News*, January 25, 1890.

Caustic Paste for the Removal of Epithelioma.—At a recent meeting of the New York Dermatological Society (*Journal of Cutaneous and Genito-urinary Diseases*, February, 1890), DR. LEWIS presented a case which had been satisfactorily treated by means of the following elaborate paste, which was first described by Dr. Bougard, of Brussels:

Wheat flour	60 parts.
Starch	60 "
Arsenic	1 part.
Cinnabar	5 parts.
Ammonium chloride	5 "
Mercuric chloride	0.5 part.
Saturated solution of zinc chloride	245 parts.

The first six ingredients are separately ground to a fine powder, and mixed in a mortar. The zinc chloride solution is then slowly added while the contents are rapidly stirred. The soft mass is then poured into an earthen pot, and, if covered, will keep in good condition for months.

In the case reported, the outer horny covering of the epithelioma was first removed with liquor potassa, the paste was then applied and allowed to remain for thirty hours, after which poultices were applied for three days. At the end of that time the slough came away, leaving a healthy granulating surface.

The Surgical Treatment of Hepatic Abscesses.—At the conclusion of these instructive lectures on the surgical aspects of hepatic abscesses, MR. RICKMAN J. GODLEE (*British Medical Journal*, January 25, 1890) submitted the following rules for the treatment of the several varieties:

1. Pyæmic abscesses do not call for surgical interference, or, if in rare cases one should point, it is only opened to relieve symptoms, but without hopes of doing permanent good.

2. The same observations apply to abscesses resulting from suppurative phlebitis of the portal vein.

3. Multiple abscesses associated with dysentery or ulceration of the bowels are very unfavorable for surgical treatment. They must, however, be opened and treated on the same lines as the single or tropical abscess, because they cannot be certainly diagnosed.

4. Single abscess of the liver, whether tropical or not, must, if it approach the surface, be opened, the following precautions being adopted:

(*a*) If it present at the epigastrium, the presence of adhesions must be ascertained before incising the liver.

(*b*) If through the chest wall, a spot must be chosen below the normal limit of the pleura; but, if by chance either pleura or peritoneum be opened, the opening must be closed with a double row of stitches before incising the liver.

(*c*) Strict antiseptic precautions must be adopted throughout, either carbolic acid or some slightly soluble salt of mercury being employed for the dressings.

(*d*) The tube must be of large size at first, and a tube of some sort must be kept in until the discharge is reduced to a very minute quantity.

If the abscess have burst into the lung, pleura, pericardium, peritoneum, or kidney, and the position of the abscess can be clearly determined, it must be opened without delay. If the position of an abscess be only suspected and the patient be losing ground, it is right to puncture the liver in the most likely situations, bearing in mind that, though usually quite harmless, a slight amount of risk accompanies this very trivial operation. This rule applies to cases in which the abscess has ruptured into any of the cavities enumerated above. If, on the other hand, whether the abscess have ruptured or not, there are no means of diagnosing the whereabouts of the matter, and the patient be not losing or even gaining ground, the surgeon should hold his hand for a time.

5. Hydatids of the upper and back parts of the liver are to be treated upon the same lines; but in cases of this sort, and in those of subdiaphragmatic abscess, it must be remembered that the diaphragm may be pushed up a very great height, thus closely simulating intrapleural suppuration.

6. Empyema, pericarditis, and peritonitis caused by rupture of an hepatic abscess or hyatid must be promptly dealt with on general principles.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

THE TREATMENT OF CARBUNCLES AND FURUNCLES WITH TINCTURE OF IODINE.

SINCE the discovery of the microbic origin of boils and carbuncles, there has naturally followed a modification in the means of treatment of these painful and, at times, dangerous affections. Knowing that they are caused by the entrance of specific microbes into the cutaneous glands, the rational means of cure must be sought amongst the antiseptics, which must be brought in contact with the focus of disease.

An interesting article upon this subject, by M. BEAUQUINQUE, appears in the *Revue Générale de Clinique et de Thérapeutique*, No. 46, 1889. The paper has especial reference to, and has the title, "The Treatment of Carbuncle of the Face by the Tincture of Iodine," but also speaks of the antiseptic treatment of furuncles and carbuncles in general. Three striking cases of carbuncle of the lip, all of them severe, are reported as having been successfully treated by the application of tincture of iodine. No more striking instances than these could have been chosen, for every surgeon of experience knows how serious an affection carbuncle in this situation is, as well as the extreme degree of suffering it causes. Of the old-time methods of treatment none is satisfactory, and all are here open to objections. Incision, whether crucial through the lesion, or elliptical surrounding it, is sure to provoke troublesome, if not dangerous, bleeding; poultices tend to increase the already extensive swelling and œdema—which themselves constitute, in some instances, a well-grounded source of alarm; and, for the same reason, the employment of the thermo- or galvano-cautery leaves much to be desired.

If the application of the tincture of iodine can lead to such happy results as those given by M. Beauquinque in the cases, and in the region referred to, it certainly must prove a valuable remedy for the affection wherever situated. The method of applying it is a simple one. The crust or film which closes the orifices of the carbuncle having been carefully scraped off, the tincture is applied several times by means of a brush or a dossil of cotton. The procedure does not cause much pain, and even in extensive cases does not give rise to toxic symptoms. For the latter reason, the tincture may in such instances be injected into the interior of the lesions.

Besides the tincture of iodine, other antiseptics have, of course, been employed in the treatment of carbuncles and boils, the principal ones being boric acid, carbolic acid, and the bichloride and biniodide of mercury. In order to insure success, it is necessary that the solution should be an alcoholic one, for water cannot gain entrance into the greasy sebaceous follicles wherein the source of trouble lies, whereas alcohol can. Of the above-named antiseptics, boric acid seems the least worthy of confidence, its germicidal power being so far below that of the others. Carbolic acid may, in severe cases, especially if injected into the centre of the lesion, or around it, produce toxic effects; bichloride of mercury, used in the same way, would give rise to severe pain.

In the tincture of iodine we have a harmless and efficient remedy, endowed with ample antiseptic power. If early applied, it is needless to say that the certainty of its abortive action is promoted.

The substitution of such a remedy for the knife, the cautery, or the poultice, is certainly a welcome improvement in surgical treatment, and is but one of the many things for which we are indebted to the study of bacteriology on the one hand, and to the development of antiseptic methods on the other.

ANÆSTHETICS.

It would be hard to find, in the whole domain of medicine, any one thing which does more toward

its retardation than absolute, dogmatic assertion based upon limited experience; and the expression, that the worst enemies to science are its own friends, finds ample illustration in the question of anæsthesia. In THE MEDICAL NEWS for November 9, 1889, we attempted to show the impossibility of saying that any one substance could and should always be employed for the relief of pain, and insisted upon the employment of one or the other not because it was chloroform or ether, but for the reason that common sense indicated which was best in each case. The opinion was expressed at that time that chloroform was the more dangerous of the two, and that it required greater care in its administration than ether; a care often almost impossible to bestow if the physician is not provided with a skilled assistant. No one can deny that all anæsthetics are dangerous, and that the functional inactivity of the perceptive centres in the brain produced by their use, if it extends to the vital centres in the medulla, may cause death. The questions are, Which drug is the safest? Which has had fewer accidents? What cases should be given ether, and what cases chloroform?

For a number of years the London *Lancet* has been most vehement in its attacks on chloroform as an anæsthetic, and has been so positive concerning its views as to endanger the standing of physicians who employed this drug. The position of THE MEDICAL NEWS has been decidedly in favor of ether, but, notwithstanding this fact, the value of chloroform in certain states has not been gainsaid; neither have the opinions of a large number of physicians, particularly in the West and South, been ignored.

The object of this editorial is to place THE MEDICAL NEWS on record as protesting against the indiscriminate language used heretofore by the *Lancet*, and its positively harmful and dangerous assertions made much more recently. Having decried chloroform as a producer of awful accidents, it now not only defends it but even goes so far as to assert, editorially, that chloroform is so safe that death is never produced unless negligence on the part of the physician is most flagrant. Such utterances endanger the professional reputation and ability of everyone who uses chloroform at any time, be the circumstances what they may. There are a certain number of instances where risks must be taken, and others in which no amount of care can put aside an accident. Further than this, the most eminently skilful operators in the world have lost cases, and therefore stand accused by the *Lancet* of killing their patients because of ignorance or carelessness. If the members of the profession are willing to expose themselves to law-suits and prosecutions for malpractice when they are so unfortunate as to lose cases under chloroform, the editorial comments in the *Lancet* possess no interest and may go uncontradicted; but if the unavoidable accidents occurring under anæsthesia are to be considered as indicative of professional disgrace, it is certainly of importance that they be not allowed to pass as generally accepted facts and a reflection of the opinions of the entire medical fraternity.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, December 3, 1889.

THE PRESIDENT, D. HAYES AGNEW, M.D., IN THE CHAIR.

DR. THOMAS G. MORTON gave a partial history of a case of

TOTAL PARALYSIS OF MOTION AND SENSATION

under the care of Dr. Sinkler, at the Orthopædic Hospital, in which he removed some weeks ago the spinous processes of the eighth, ninth, tenth, and eleventh vertebræ, with a decided improvement in the symptoms. Dr. Morton commented particularly on the ease with which the operation was performed, the only instruments required being a knife and a pair of long, sharp bone-cutting forceps.

In the discussion which followed, DR. WILLIAM HUNT remarked that he had been present at the operation and was surprised at the amount of oozing. Whether this was the result of hypostatic congestion or belonged naturally to the part, he could not say. Under the use of hot water it ceased. He inquired if any one knew whether in man or animals the cord pulsates as the brain does? In this case the cord did not pulsate. He had had no other experience with the living cord, but supposed it is through the circle of Willis acting upon the full cranial contents that the familiar pulsations of the brain are produced.

DR. J. EWING MEARS said that as we are now just at the beginning of our experience in spinal surgery, every case in which operation is performed increases our knowledge. Some months ago he reported to the Academy a case of fracture of the first lumbar vertebra in which he removed the laminæ, articulating processes and spinous process of the vertebra, and in this way relieved the pressure, although he was unable to reduce the dislocation.

The fracture had been produced by a fall from a window during an epileptic seizure. There was complete paralysis of sensation and motion when the patient was brought to the hospital. At the operation he did not note any pulsation of the cord, nor was the hæmorrhage unusually free. The condition improved after the ope-

ration. Motion and sensation returned, and when he last heard from her she was able to go about on crutches.

Dr. DeForest Willard said that Dr. Burrell, of Boston, who some months ago operated on the spinal column for pressure paralysis, had a pair of forceps made with the lower blade flat, while the upper blade was the cutting one. With the ordinary bone forceps he thought that there might be some danger of wounding the cord.

Dr. Willard then requested the opinion of the Fellows present, as to the best course to pursue in a case of a bad double crush, such as he had seen a few days ago; a man with both legs run over, so weak that he was apparently dying, with a feeble, fluttering pulse and yet with bleeding sufficient to require the application of rubber tourniquets. The pain of the tourniquets seemed to cause as much depression as an operation, yet the patient was too sensible to permit operation without ether. His condition was such that the administration of ether would probably have been followed by death in a short time. The man gradually failed and died in less than twenty-four hours, never reacting sufficiently to make it safe to operate. Both thighs were comminuted for some distance and there was concealed hæmorrhage, the skin not being broken to any extent. It is difficult to know what to do in such cases, whether the shock of a rapid operation would be greater than the loss of blood occasioned by delay, or more depressing than the excessive pain of a tourniquet. If the wound is large, local pressure with antiseptic packing is less painful than compression above.

Dr. Morton, in reply, said that he had had considerable experience in such cases, and when bleeding occurs from lacerated crushed tissues he always tied the bleeding vessels in the wound if possible; if this was not practicable, he then cut down and ligated the main arteries above the region of injury. He would never apply a tourniquet, because of the pain, and on account of the injury to the tissues so constricted.

Dr. Hunt agreed with Dr. Morton in regard to the tourniquet. From a surgical standpoint it is our duty to try to save life, but from a sentimental one he should rather let the patient alone after taking away all sources of irritation and suffering and wait for reaction. To operate at once would be almost certain death. If reaction occurred it might become our duty to operate. He confessed that in those cases of terrible multiple maiming, especially in children, it was a relief to him to hear that death had taken the patient from our hands.

Dr. F. H. Gross had several times performed double amputation in such cases, but had not had the patients die upon the table, although they came very near it, and in one apparently hopeless case death took place on the following day. During his last term of service at the German Hospital, he had under his care a man who had fallen a distance of over one hundred feet while painting a church steeple, striking the roof and then bouncing like a ball from the telegraph wires upon an iron railing on the sidewalk. He sustained severe lacerations and was in profound shock. Valuable time was lost in persuading his friends to have him submit to two necessary amputations. Dr. Gross removed one leg and one arm near the shoulder joint. The other arm and leg were also fractured, but the injuries there were not compound, although the bones about the ankle felt like a bag of broken crockery.[1] In his military experience, it seemed to him that men suffered more profoundly from shock when a limb was entirely carried away than when both soft parts and bone were severely lacerated and crushed by the missile.

Dr. Mears then referred to two

OPERATIONS FOR CHRONIC OSTEOMYELITIS.

The first case was that of a girl twenty-two years of age, in whom he trephined the radius in the lower third. He curetted the medullary canal, carrying the instrument upward three or four inches, cleared out the cavity and put in a drainage-tube. The patient recovered, and is now an assistant in the hospital, with a useful arm. Before the operation the arm had been useless and the seat of great pain.

Four weeks ago he performed excision of the hip-joint, removing the head and neck of the bone and scraping the acetabular cavity, which was slightly involved. After removing the head of the bone, he found the femur to be the seat of osteomyelitis; he therefore removed two and a half inches more of the bone in the hope of reaching sound bone, but in this was disappointed. He then curetted the medullary canal, carrying the curette three or four inches toward the lower extremity of the bone. The patient now was in excellent condition, suppuration has decreased greatly, she is sitting up, and the general condition is better than for months. What the ultimate result will be, and whether or not the limb will be a useful one, he was unable to state.

In the discussion which followed this report, Dr. Willard said that about the first of last May he had excised a hip in which the femur presented the condition described by Dr. Mears. He removed several sections of bone until he got below the lesser trochanter, when, finding that the periosteum was loose and that the signs of osteomyelitis extended two or three inches further, he thought it unwise to remove more of the bone. He curetted it thoroughly, dressed it antiseptically, and in three months it had healed almost entirely. The child was in good condition, but there was some thickening about the femur that made him suspicious. He had seen the child again to-day. The wounds had reopened and the disease was progressing down the femur. Under antiseptic dressings, we often secure prompt healing of the wound, while at the same time the disease steadily creeps on. He thought that a better operation in such a case would have been amputation at the hip-joint.

Dr. Morton referred to a similar case on which he had operated many years ago, at the Pennsylvania Hospital. There was great shortening, with a useless limb. The patient died subsequently from phthisis.

He said that Dr. W. J. Duffy was the first to amputate at the hip-joint for the condition which has been described. This operation was performed at the Philadelphia Hospital about 1840, and the patient recovered.

Dr. William G. Porter then asked the opinion of the Academy on the treatment of gangrenous hernia. A week ago a woman was admitted to the Philadelphia Hospital with a hernia which had been strangulated four

[1] The patient recovered.

days. On opening the sac, Dr. Porter found a mass of gangrenous omentum and two or three inches of gangrenous bowel. He relieved the stricture, and allowed the bowel to remain in the wound. He deliberated some time as to the best course to pursue, whether to perform excision of the bowel, doing the old-fashioned operation with the Lembert suture, or to do the modern operation of lateral anastomosis, or to allow the formation of an artificial anus, to be followed later by an operation for its closure.

It seemed to him that we do not know what is exactly the best procedure in these cases. Each case must, of course, be studied by itself. After a patient has suffered with an unrelieved hernia for four days, she is not in a condition to stand any prolonged operation. He had recently come across the report of three cases, in which the primary operation was done with success. His experience with these cases has been unsatisfactory. The case just referred to lived nearly a week. Another, that of a boy with strangulation for several days, lived twenty-four hours. In still another case there was gangrene of a large portion of the omentum, but simply a small perforation in the bowel. This he pinched up, placed a ligature around and returned to the abdomen. There was one passage from the wound, and after that there was no further trouble. He had seen three or four cases in which there were gangrene, perforation, and fæcal extravasation. All these cases died.

Dr. Morton said that a patient with gangrenous hernia is generally so exhausted that any operation of magnitude, such as laparotomy, would be impracticable, and we have to be content with removing the gangrenous portion of the bowel, and then making an artificial anus.

Dr. Mears thought this question one of great importance, and, as Dr. Porter had said, each case must be judged on its individual merits. The question had been fully discussed at the last meeting of the American Surgical Association, and there were various and diverse opinions expressed. There seemed to be no definite decision reached.

Dr. Porter said that some time ago he was called to the hospital to see a woman who had a hernia strangulated for about a week. It was a large, right inguinal hernia. The Resident had had no trouble in restoring it by taxis, without ether. The stercoraceous vomiting, however, continued, and diarrhœa set in at the same time. This was a combination he had never seen before. After consultation with two of his colleagues, he concluded that it was right to give her the chance that laparotomy would afford. He made a median incision, and explored all the hernial openings. There was no peritonitis, no evidence of rupture, and no signs of intussusception. The woman's condition was so critical as not to warrant turning the intestines out and examining them systematically. The operation was completed, and the woman died shortly afterward. At the post-mortem there were found adhesions between three coils of intestine, which had kept up the strangulation. With the exception of these adhesions, the bowels were in good condition.

CORRESPONDENCE.

ST. LOUIS.

To the Editor of The Medical News,

Sir: Our St. Louis Medical Society, like most similar organizations, has had many variations as to the interest of its meetings and the value of its discussions. At times there have been stormy scenes, when it seemed more like a meeting of ward politicians, and when the discussions were characterized by uncomplimentary personalities that were utterly unworthy of a company of scientific gentlemen assembled in the interest of a profession which they all claimed to love. At other times, the work done there has been such as would reflect credit upon any society. At all times its offices of honor have been much prized and eagerly sought

A year ago there was a great disturbance at the annual election; charges of illegal voting being freely made on both sides, and two sets of officers claiming that they were the choice of the Society. It resulted in a temporary split of the Society, two meetings being held at different places by the two factions for several successive weeks. At length, however, the smaller division voted that in the interest of harmony in the profession they would discontinue their separate meetings. Some returned and took part again in the regular meetings of the old Society, while others united with a number of physicians, not members of the Society, in the organization of the St. Louis Academy of Medicine.

On December 28, 1889, the annual meeting of the old Society took place. After a brief address by the retiring president, the reports of the various officers were read. It appeared from the report of the secretary that the average attendance at the weekly meetings during the year was over forty.

Before the meeting, it had been currently reported that there would be great excitement over the election of president, inasmuch as it was asserted that four specialists on insanity and nervous diseases were aspirants for the office. As a matter of fact, when the ballot was taken, without nominations being made, three of these gentlemen had large votes, but none of them had a majority. On a second ballot, however, Dr. J. K. Baudry secured 42 of the 83 ballots cast, and was thereupon declared elected. The other officers were: Dr. F. D. Mooney, Vice-President; Dr. Garland Hunt, Treasurer; Dr. W. Blickhahn, Recording Secretary; and Dr. E. S. Smith, Corresponding Secretary. Following the meeting a large number of the members adjourned to the supper-room of one of the most popular restaurants, where a banquet was spread, to which full justice was done by all. Later, toasts were drunk and responses made, and it was a late, or rather very early hour, when the festivities terminated.

Nearly all, or perhaps all, of our large cities, and many of the smaller, have, in more or less successful and efficient operation, training schools for nurses. We have one here, which has done admirable work in connection with the City Hospital. The course of instruction lasts during two years. Those in charge have been most painstaking and conscientious in their work, and very careful and exacting in their requirements, so that the physicians of the city have learned that the diploma of the Training School for Nurses is a full guarantee of ability and reliability.

Without disparaging in the slightest degree the support given by others, it is only just to say that in large measure the success of this institution is due to the indomitable energy and wise tact of the president of the Ladies Board of Managers, Mrs. W. H. Pulsifer, herself a thoroughly experienced and cultivated physician. A large and suitable building has been erected at a convenient distance from the City Hospital, which is occupied as a "Nurses' Home," all the pupil nurses having their rooms therein, as well as some of the graduates.

Last summer, the officers and staff of St. Luke's Hospital organized another training school in connection with that institution. They have a special building adjoining the hospital for the residence of the pupil nurses, and propose to send out their nurses with diplomas after one year's service in the hospital, during which they will receive lectures from the staff, and clinical instruction in the wards and private rooms of the hospital.

I understand that a third training school is to be established in connection with the Protestant Hospital. Of this I will give further details in a future letter.

Among the items of journalistic interest, I may mention that with the January issue the *St. Louis Polyclinic* assumes the title of the *St. Louis Courier of Medicine*, the publication of which was discontinued a year ago, as mentioned in a former letter. The faculty of the Post-Graduate School of Medicine have disposed of their interest in *The Polyclinic* to Dr. L. A. Turnbull, who edited it for them, and he having secured the coöperation of some of those formerly identified with the *Courier*, takes that name in preference to the other.

NEW YORK.

To the Editor of THE MEDICAL NEWS,

SIR: At this season of the year our medical societies generally experience an increase in activity, and the members filled with good resolutions for the new year, and perhaps urged on by the enthusiasm of newly elected officers, are wont to bring forward an array of peculiarly interesting papers. The County Medical Association enters upon another year's work under very auspicious circumstances, having an active membership of four hundred and thirty, which is an increase during the past twelve months of seventy per cent.

A practical paper on "The Treatment of Typhoid Fever," read before the Academy of Medicine the other evening, by Dr. W. H. Thomson, brought out a very instructive discussion. In the cases which formed the basis of his paper, the eruption was chiefly conspicuous by its absence; diarrhœa was unimportant; and some of the cases were even marked by obstinate constipation. He did not confine himself to any one method of treatment; but when the fever was excessive, employed baths, according to the method of Liebermeister; when tympanites required attention, administered the resin of turpentine; and for the diarrhœa and gastric disturbances, made use of large doses of the subcarbonate of bismuth. The patient was fed on milk and lime-water, and digestion aided by giving saccharated pepsin, usually in conjunction with dilute hydrochloric acid. This milk diet was well tolerated in most instances, and it was rarely necessary to resort to opiates for the control of diarrhœa; and he attributed this to the excellent antiseptic properties of lime-water. He denounced all the antipyretics of the coal-tar series, including quinine, as highly dangerous on account of their depressing action on the heart.

Dr. E. G. Janeway was inclined to be sceptical in regard to statistics bearing upon the treatment of this disease, because he had seen many cases abort. He sounded a note of warning against the use of strophanthus, for it had proved a delusion and a snare. In some cases it had produced a very exhausting diarrhœa, which ceased on discontinuing the drug, and returned when the medicine was resumed. Independently of this disagreeable feature, it was not the weapon for one to use in fighting so serious a disease; for its preparations were very uncertain, so much so, that he had known of a half drachm of the tincture having been taken without any appreciable effect.

Dr. A. Jacobi had noticed this dangerous peculiarity of strophanthus, and had found that even the preparations furnished by Merck and Squibb were widely different. He did not doubt the frequency of the abortive form of typhoid among children, but he considered it very uncommon among adults.

Dr. S. Baruch, the champion of Brandt's cold bath treatment of typhoid fever, again urged a more general recognition of the advantages of this method. When the temperature reaches 104° the patient should be immersed in a bath at 65°, and kept there for fifteen minutes; and this bath is to be repeated every three hours until the fever keeps within more moderate limits.

While bringing forward this method of treatment with great earnestness and candor, Dr. Baruch does not tell us what is to be done with patients whose vitality is at so low an ebb that they cannot react after this vigorous treatment.

As is usual, the question of diet brought out various opinions, most of those present resuming solid food very cautiously, and only when the patient was well along on the road toward convalescence. Dr. G. L. Peabody took pity on the poor fever-worn sufferer, and even before his temperature had quite reached normal, if he were very hungry, allowed him a very little chop or beefsteak once a day. He had made this innovation with some trepidation, but had seen no bad results from it; and it was not unreasonable to suppose that the intestines were relieved of considerable work, as this food produces much less refuse matter than an exclusive milk diet. As regards stimulants, he prefers "the wine of America"—whiskey.

This is an age of iconoclasm in medicine, and our cherished household gods must go; and so it is not surprising to hear that not only must the old-fashioned beef-tea be banished from the sick chamber, but even that made from Liebig's extract can no longer hold a place in the confidence of good orthodox physicians; for, Dr A. H. Smith tells us it is "about the most homœopathi diet imaginable."

In these days of sneezing and aching bones, it is but natural that those of us who are well enough to be around, should turn our steps toward the Academy of Medicine to listen to a paper on "La Grippe." Never was an audience better prepared to discuss the subject from the standpoint of personal experience. This time the speaker was one of our energetic medical women—Dr. Louise Fiske Bryson—who gave a sketch of various epidemics of influenza which had visited different parts of the

world, and stated that just one hundred years ago this country had been favored by a similar visitation. She called attention to the fact that although the total number of deaths must be large, on account of the great number of persons affected, the mortality was only two per cent. No locality was exempt from it; for it visited mountains as well as valleys, and even those in mid-ocean did not escape it. It was not infectious, but there could be no question about its being contagious. The symptoms were about the same in every epidemic, and the treatment consisted usually in the administration or calomel or some other cathartic, along with quinine and antipyrin. She thought that these epidemics of influenza were due to peculiar atmospheric conditions, and certainly the remarkable weather of this season impressed the hearers with the soundness of this theory. Although it has been announced that a special bacillus has been found in connection with this epidemic, we are not likely to derive much benefit from this discovery, for the influenza is rapidly on the wane. Dr. Bryson gave this advice to those who are attacked by "la grippe:" "The use of alcohol is forbidden. Go to bed, and stay there for five days; eat light food; use foot-baths; and let there be quiet of mind and body, together with an entire absence of friends, save those who are in immediate attendance upon you." Judging from some cases which have been ushered in by sudden and very acute symptoms, which passed away almost as quickly as they came, the advice "to stay in bed for five days," is certainly somewhat dogmatic.

In connection with the subject of the influenza, it is amusing to note the varying capacity for work displayed by individual physicians. One well-known medical gentleman triumphantly announced that during the height of the epidemic, he saw in one day no less than eighty patients; another physician said that forty-four had wanted him, but that it was "a physical impossibility to see them all;" while a third complained that he had been completely exhausted in attending to twenty-six patients.

CINCINNATI.

To the Editor of THE MEDICAL NEWS,

SIR: Dr. C. D. Palmer, of this city, has been made the victim of a malpractice suit for the sum of $10,000. The charge is that he negligently permitted a fragment of a large needle to remain in a patient upon whom he had performed perineorrhaphy. Dr. Palmer admits that he permitted the fragment of needle to remain as alleged, but denies that it was through negligence.

The facts in the case are about as follows: In April, 1888, the defendant performed perineorrhaphy upon the woman who now makes the complaint. At the close of the operation, he discovered that the extremity of his needle had been broken. He could not well determine whether the fragment had remained in the soft parts of the patient or had fallen to the floor. As the patient was then in a much prostrated condition from anæsthesia, he did not deem it prudent to prolong the operation for the purpose of search. As the fragment was not found after the operation, he feared that it had been retained, and for some time interrogated the patient for symptoms of its presence, and made such examination as the recently united parts would justify. Before, however, a proper time came for the thorough examination, Dr. Palmer met with a serious accident, being thrown from his carriage and so severely injured that, for months, his life was despaired of, and for more than a year he was prevented from resuming the practice of his profession.

In the meantime, the woman began to suffer severe pelvic pains. Having no suspicion of the possible presence of a foreign body, she fancied that her pain was due to ovarian disease, and applied to Drs. W. H. Wenning and George E. Jones, of the St. Mary's Hospital, to have the fashionable operation of oöphorectomy performed. The ovaries were found free from disease, and it was decided to repair the perineum still further, and it was while making the denudation that the operator discovered the fragment of needle, about an inch in length, and removed it. Its removal was followed by complete, although not immediate, relief.

Dr. Palmer is a leading specialist of our city. He is Professor of Diseases of Women in the Medical College of Ohio, Gynecologist to the Cincinnati and Good Samaritan Hospitals, and an Ex-President of the Cincinnati Academy of Medicine. His opinion is always expressed in clear and decisive language, and is always regarded as authoritative. The misfortune could not, therefore, have fallen upon one more unlikely to be guilty of the charge. The fact that he permitted the needle to remain in the tissues until the time of his injury is, in the eyes of the local profession, sufficient evidence that this was the proper course to pursue, and no one doubts that had he been permitted to continue his treatment of the case, it would have been conducted to complete recovery at a proper time.

Of course a case of this character could not occur without exciting much unfavorable comment, particularly against the surgeons who performed the second operation. Some individuals go so far as to accuse them of wilfully inciting the prosecution. There is, however, no ground for such accusation. Had it not been for the presence of a special nurse employed by the patient, and not connected with the hospital, the fact that a foreign body had been removed would probably never have been known outside the operating room, and the emphatic assertion of the gentlemen who performed this operation that they made no comment upon the discovery of the needle-point is, in a measure, corroborated by the fact that fully six months elapsed before litigation was decided upon.

The affair is an exceedingly unfortunate one throughout, and one which, if reports be true, is now regretted as well by the party bringing the suit as by all those who are involuntarily brought into it.

A very unhappy and unfortunate episode occurred last Thursday, which promises to add vigor to the proceedings against Dr. Palmer. In the *Lancet-Clinic* of Jan. 25th, the Editor, in referring to the case, took occasion to condemn the attorneys connected with it in language which is, perhaps, more vehement than judicious. He denounced the proceedings as the most "contemptible, villanous attempt at blackmail" of which he had heard, saying, also, "Our ardent hope and wish is that the doctor will at once take measures to turn the tables on these legal buzzards who, for a possible contingent fee, would attempt to rob him, and who, by their acts, have tried to bring a highly honored and honorable practitioner of the medical profession into contumely and con-

tempt. Out upon such villains, unworthy members of a dignified profession!"

The attorneys against whom this charge was made are young but prominent members of the Bar, and have heretofore borne a reputation for honest dealing; they doubtless took charge of the case in good faith and without thought of blackmail. So incensed were they, however, at this charge, that they promptly repaired to the office of the *Lancet-Clinic* and proceeded to make a most cowardly attack upon the Editor, Dr. J. C. Culbertson, whom they found alone and unprotected. But the worthy editor proved more of a pugilist than they anticipated, for he disarmed one of them of his weapon —a raw-hide—pommelled him over the head with it, and forcibly ejected him. His other assailant was in the meantime waited upon by the robust foreman of the printing office, who had been attracted by the uproar. A warrant was promptly sworn out by Dr. Culbertson, and the two attorneys were placed under arrest.

VIENNA.

To the Editor of THE MEDICAL NEWS,

SIR: Just now the influenza monopolizes the attention of the Vienna medical world. Everybody has had it, the hospitals are filled with its victims; of the American colony eighty per cent. were sick, or are so now—the royal family, the professors and students succumbed; so many of the latter that lectures were suspended.

The grandest man in the faculty here is undoubtedly Billroth, the surgeon. He is tall and well built though slightly stooping, has a fine head, with a large aquiline nose and clear eyes, with rather heavy eyelids. Scanty white hair makes his forehead seem very high, and a great flowing white beard conceals the lower half of his face. He speaks in a rather low tone, but every sentence is clearly cut. On the first of May, 1889, he celebrated his sixtieth birthday, and received a grand ovation from the city as one of its most honored citizens.

His clinic room is small, seating about 250 students very uncomfortably. The operating space is 15 x 25 feet and rectangular; in it are two tables, for the number of patients is so great that often while Billroth operates at one table the assistants work at a minor case at the other. Laparotomies are of daily occurrence, and on one morning I saw an echinococcus of the liver removed, a strangulated hernia liberated, a uterine fibroid excised by the Briesky method, and an ovarian cyst taken out.

Dr. Zeman, the great favorite of Americans in Vienna, who has given most excellent courses in gross pathology to classes made up of foreigners only, leaves his position as first assistant to the chair of pathology in March. He will take charge of two suburban hospitals.

The clinic of Professor Nothnagel on internal medicine is also a favorite one, but the professor is now very ill from an attack of influenza complicated by pneumonia.

Although Nothnagel is one of Europe's highest authorities on brain lesions, even he makes mistakes. He recently showed a case in which all the symptoms of *meningitis suppurativa* were well marked, yet the post-mortem proved it to be a venous varix in the optic thalamus. Another case that he demonstrated as progressive paralysis, on dissection was found to be an abscess in the parieto-occipital region. In the case of venous varix Nothnagel stood at the post-mortem almost sure of verifying his diagnosis, but when Professor Kundrat removed the calvarium and everything looked normal, Nothnagel was greatly surprised. On the next day he gave a brilliant lecture on the uncertainty of diagnosis.

In the treatment of pleuritis they are very partial here to dry cups. In Nothnagel's clinic the cups are placed over the seat of the disease early in the case, and they greatly diminish the pain and make healing more easy. For large effusions, that are known to be serous, the "Thirst Treatment" has found considerable favor. The patient gets nothing but dry food, dried bread, smoked meat, etc,, so that he receives as little water as possible. He become very thirsty at first, but soon becomes somewhat accustomed to the diet. On the first day his urine is quite scanty, but on the third or fourth it increases and the exudation in the pleural cavity grows rapidly less, all the tissues yielding their moisture, but those in a pathological state yielding up the greater portion.

That rare disease, *actinomycosis*, is quite common in Professor Albert's surgical clinic, for in the past four months he has shown more than a dozen cases. In most of them it was localized as an abscess on the lower jaw, but in one case there were several large abscesses in the liver, there had been perforation into the lung and large quantities of pus were expectorated. The spleen was also involved and the patient finally died of peritonitis. The lumbar vertebræ were filled with little nests of the germ, and there was no healthy organ in the body except the heart. The diagnosis is easy, for in the pus from an actinomycotic abscess, hard granules as large as a grain of sand and greenish in color can be found; on microscopic examination they present "the appearance of a wheel with from twenty to forty spokes." The treatment must be heroic, for after the alimentary canal has been infected the prognosis is fatal. In every case of suspicious abscess the pus is examined carefully for the germ.

Three excellent docents were promoted to professorships at Christmas time—Professors Lorenz, Maydl, and Fritsch. Lorenz has long been an authority on orthopædic surgery, Maydl is the surgeon of the Policlinic and a most skilful operator, while Fritsch is less well known. Lorenz and Maydl are both former assistants of Professor Albert.

There are about a hundred American physicians in Vienna at the present time and several homœopaths. Many courses in gynecology, surgery, and ophthalmology are given in English for their special benefit, and most of the docents and assistants speak English. Foreigners work principally with the docents and assistants, as these may give practical courses for advanced men, while the professors have time for nothing but the regular lectures for students. Thus we get into the wards and examine the patients in their beds, while the Austrian student rarely comes to the bedside. For this instruction and practice we pay about forty cents an hour, although we always have another hour before the docent comes in, to examine and thoroughly study the cases.

There is so much pneumonia prevalent here now, and so much pleuritis that differential diagnosis is at times almost impossible, and the professors are now investigating the value of urinary analysis in the differentiation. They place considerable importance upon the amount of chlorides in the urine, and in many cases make the

diagnosis depend almost wholly on the nitrate of silver reaction.

Professor Kaposi, the dermatologist, still adheres to the theory that lupus is non-tuberculous. He spends an hour each term trying to prove that the bacilli found in lupus get there accidentally, and that they are rarely found. He undoubtedly has remarkable success in the treatment of lupus, for he removes each little nodule by a sharp spoon, and though he does not believe it tuberculous he treats it as though it were. He shows twenty or thirty cases of *lupus vulgaris* every week. He also has a case of leprosy which has been in the hospital for many years, mingling with all the patients, and this certainly proves that the dread disease is non-contagious, for no other case has been discovered here in all that time. This poor man is indeed an awful sight; his eyes are gone, his fingers are mere stumps, his face looks like that of a corpse which has been in the water for a week, and all his movements are slow and trembling. Great numbers of scabies cases are treated here, and Kaposi's favorite prescription gives excellent results:

R.—Adeps	100 parts.
Sapon. virid. . . .	50 "
Naphthol	15 "
Cretæ alb. pulv. . . .	10 "

Apply very thoroughly over the entire affected area, and rub it over the rest of the body also. One application generally suffices and no bath is necessary as preliminary treatment. The patient is not washed for a week, and at the end of that time a cure is almost certain.

NEWS ITEMS.

The Mott Memorial Library.—From a circular sent out by the Secretary of the New York State Medical Association, we learn that the Society has joined interests with the Mott Memorial Library. The coalition brings together about 13,000 volumes at No. 64 Madison Avenue, a locality that will be convenient for the seven hundred members of the Association, when in New York City. An effort will be made to secure the services of a librarian as soon as possible, in the belief that in proportion as the books already owned can be utilized, there will be a constant and growing flow of volumes to the Library.

Surgery on a Sick-bed.— Dr. Hulse, of Bay Shore, Long Island, is reported to have performed a surgical operation on a patient while himself sick in bed. The incident, as described by the injured patient, shows that men of heroic mould are not wanting. A young man shattered his left hand by the accidental explosion of a shotgun. He was temporarily cared for at a life-saving station, and then conveyed across the bay to Bay Shore, and to the house of Dr. Hulse, who was at the time suffering from pneumonia and confined to his bed. Messages were sent out to the other physicians of the neighborhood, but none of them could be secured for the immediate treatment of the wounded man. The wound was judged by Dr. Hulse to demand an amputation of the hand without delay. He accordingly directed that the patient be placed across the bed on which he himself lay, and, being bolstered up with pillows, proceeded to amputate the hand and dress the wound. The sick physician was suffering acutely during the operation.

New Appointment.—Dr. Frank Ferguson, Pathologist to the New York Hospital, has been elected Professor of Pathology in the New York Post-Graduate Medical School and Hospital.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 11 TO FEBRUARY 17, 1890.

SMITH, JOSEPH R., *Lieutenant-Colonel and Surgeon.*—Is granted leave of absence for twenty days, to take effect about February 10th.—Par. 1, *S. O. 15, Headquarters Department of Arizona*, February 8, 1890.

By direction of the President, LOUIS W. CRAMPTON, *Captain and Assistant Surgeon*, is detailed as a member of the Army Retiring Board at Chicago, Ill., convened by War Department Order dated November 18, 1889, published in S. O. 269, A. G. O., November 18, 1889, from Headquarters of the Army, vice Henry McElderry, Major and Surgeon, hereby relieved.—Par. 9, *S. O. 36, A. G. O.*, February 12, 1890.

By direction of the Secretary of War, the retirement from active service, on February 9, 1890, by operation of law of ANDREW K. SMITH, *Colonel and Surgeon*, under the provisions of the Act of Congress approved June 30, 1882, is announced. Colonel Smith will proceed to his home.—Par. 1, *S. O. 34, A. G. O., Washington, D. C.*, February 10, 1890.

By direction of the Secretary of War, leave of absence for two months is granted HENRY R. TILTON, *Major and Surgeon*, to take effect upon his being relieved from duty at the U. S. Military Academy, West Point, New York.—Par. 6, *S. O. 34, A. G. O., Washington, D. C.*, February 10, 1890.

By direction of the Secretary of War, the extension of leave of absence on surgeon's certificate of disability, granted LEONARD Y. LORING, *Major and Surgeon*, in S. O. 268, November 16, 1889, from this office, is still further extended two months, on surgeon's certificate of disability.—Par. 7, *S. O. 34, A. G. O., Washington, D. C.*, February 10, 1890.

By direction of the Secretary of War, CHARLES R. FLETCHER, *Lieutenant-Colonel and Surgeon*, is relieved from duty as Examiner of Recruits in New York City, and will report to the commanding general Division of the Atlantic, for duty as Attending Surgeon in that city.—Par. 1, *S. O. 33, A. G. O., Washington*, February 8, 1890.

By direction of the Secretary of War, HENRY MCELDERRY, *Major and Surgeon*, is relieved from duty at Fort Wayne, Michigan, and will report to the Superintendent of the U. S. Military Academy, West Point, New York, for duty as Post Surgeon, relieving Henry R. Tilton, Major and Surgeon, who, being thus relieved, will report in person to the commanding officer, Fort Wayne, Michigan, for duty at that station.—Par. 13, *S. O. 33, A. G. O., Washington, D. C.*, February 8, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING FEBRUARY 15, 1890.

BATES, N. L., *Medical Director.*—Ordered to the Naval Hospital, Mare Island, California.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

LESIONS OF THE CAUDA EQUINA.

Hæmorrhage into the Cauda Equina. Fracture of the Spine with Hæmorrhage into the Cauda Equina. Fracture of the Spine with Hæmorrhage into the Lumbo-sacral Spinal Cord and Cauda Equina.

A Clinical Lecture,
delivered at the Philadelphia Hospital, November 23, 1889,

BY CHARLES K. MILLS, M.D.,

NEUROLOGIST TO THE PHILADELPHIA HOSPITAL; PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM IN THE PHILADELPHIA POLYCLINIC.

TO-DAY your attention will be directed to three cases of injury of the lower part of the vertebral column, the lesions in all affecting the leash of nerves called the cauda equina. A glance at a specimen of the back bone with the spinal cord and its nerves in position, shows the considerable length of the portion of the canal in which the cauda equina hangs—six inches at least. This is one of the best protected spaces in the human body. The spines, arches, and bodies of the vertebræ are of greater bulk and strength than elsewhere, and dislocations and fractures of the vertebræ can only result from the application of a great crushing, twisting, or rending force. Injuries to this part of the human framework, however, while not common are not extremely rare, because it is often exposed to certain accidents during the performance of heavy labor, and also because in falls from heights, or in severe blows or crushes, hæmorrhage into this region is particularly likely to occur. Occasionally also lesions of the cauda equinal space are secondary to disease or injury of the spinal column, membranes, or cord at a higher level; as the result, for example, of a fracture or dislocation, or, at least, in connection with either of these injuries, a hæmorrhage may take place in the dorsal cord, and the blood find its way down the smooth intra-spinal spaces to the lowest and widest portion of the canal; or, an inflammatory process may extend along the membranes to the cauda equina.

Comparatively little attention has been paid to traumatic or other lesions of the cauda equina until the last two or three years. Cases have been reported from time to time, a few with post-mortem records. Not a few of the cases without autopsies which are to be found in surgical literature, evidently examples of affections of the cauda equina, are reported under other names, as, for instance, concussion and myelitis. The most systematic and valuable papers on this subject are those of Thorburn,[1] of Manchester, England. In this country Osler[2] has reported a few cases of disease or injury to the conus medullaris or cauda, and I have also put on record two or three traumatic cases.[1] In the papers of Thorburn the literature of the subject has been collected, but it is meagre.

Diseases and injuries of the cauda equina have both a scientific and a directly practical interest. Their study throws light upon some questions in sensory, motor, trophic and visceral physiology; as, for example, the exact cutaneous and muscular distributions of certain nerves, and the position of anal, vesical, sexual, or other centres in the spinal cord. They are, in fact, often excellent experiments for determining the functions of spinal segments and nerves. Practically they are of great importance for diagnosis, prognosis, and treatment. Some of the problems of diagnosis will be treated of after the presentation of the cases. As regards prognosis, while some of the cases are of the greatest possible seriousness, resulting fatally or causing extensive and permanent paralysis, others which at first have an entirely hopeless appearance make partial and occasionally almost complete recoveries. One question in the treatment of these cases is whether or not trephining should be performed, a problem by no means easy to decide. Thorburn advocates operation in most cases. On the one hand we have a region of the spinal column chiefly containing nerves, and not the more vital and delicate cord, and, therefore, operation offers considerable hope and is less dangerous. On the other hand, however, cases apparently desperate and hopeless at first, under rest, absorbents, electricity and time, make such approximate recoveries as to throw doubt upon the value of active surgical interference. The cases which will be presented this morning illustrate both sides of this problem of prognosis and treatment. Two of them have made partial recoveries from conditions of almost complete sensory and motor paralysis, although they are by no means entirely relieved from suffering and disability. The third case is one in which injury, probably a fracture, accompanied or followed by hæmorrhage, has left the patient in a hopeless condition of paralysis and suffering, and is probably one in which if operation had been early performed, much of this misery and helplessness might have been saved.

The first patient I bring before you, as you see, walks about with some spryness, but has a peculiar, limping, thumping gait, the motor defect which causes it being seemingly more marked in one limb than the other. The following are the notes of his history:

CASE I. *Hæmorrhage into the cauda equina from traumatism: involvement of certain sacral nerves; marked anæsthesia in the distribution of the small sciatic, pudic, inferior hæmorrhoidal, and inferior pudendal; imperfect anæsthesia in other areas; paralysis in some of the muscles from the sacral segment: vesical and anal symptoms; great improvement.*—M. H., aged forty-four,

[1] Brain, January, 1888, and Medical Chronicle, April, 1888.

[2] THE MEDICAL NEWS, December 15, 1888, and Journal of Nervous and Mental Diseases, August, 1880.

[1] Therapeutic Gazette, May and June, 1880.

white, born in Ireland, a laborer, in August, 1887, while carrying a hod, fell from a scaffold twenty-five feet from the ground, and landed on his feet. He broke no bones, but could not walk. He was taken in an ambulance to the German Hospital, where he remained four months. For the first fifteen hours he is quite sure he had normal sensation in his legs, which he could also move up and down without difficulty, but during this time he had great pain in his back, especially when he attempted to move. He also had pain in the pelvis and in the upper gluteal regions. After fifteen hours he began to have pains and cramps in the left foot and leg, which were drawn. The leg also became swollen and blue. The right leg then developed the same symptoms, and both were drawn up and swollen, and blue to the hips. This condition made him practically helpless; his legs had to be lifted about when a change of position was desired.

His limbs began to improve, and they are now very much better. After the first fifteen hours he had incontinence of urine, and has been troubled with this ever since to a greater or less degree; now but slightly. For the first six months his bowels were constipated or torpid, and since that time he has suffered at times from incontinence of fæces. A tingling sensation is felt in the legs, most marked in the calves, posterior part of the thigh and buttocks, and in the left leg. In this leg he also has at times the sensation of a small stream of water flowing down the inner side of the thigh and leg. The knee-jerk is exaggerated in both legs. He says that both of his legs increase in size at times, and that the tingling sensations also are sometimes worse. He suffers sometimes from vertigo, particularly in the afternoon, but otherwise, he says, he is particularly well. His legs are not atrophied. On the posterior aspect of each thigh is a limited area of complete anæsthesia, represented in Fig. 1. The defective sensation is over the posterior central portion of the upper thigh, and the gluteal and sacral regions. It also extends to the perineum, scrotum, and penis, as shown in Fig. 2.

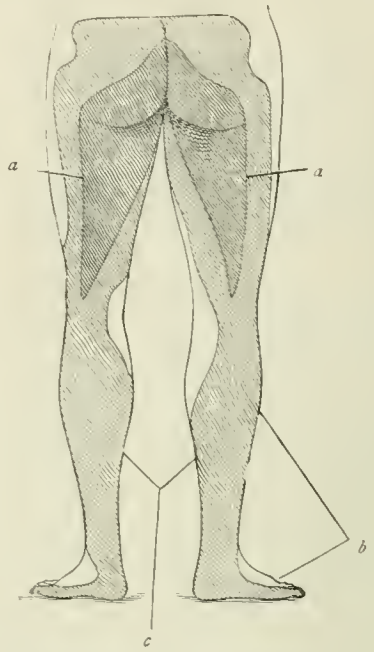
Let us now examine with some closeness the present condition of our patient as to motion, sensation, the state of his bladder, rectum, etc. He has fairly good use of his limbs, and is now working about the hospital. He uses his sartorius, quadriceps, abdominal, and pelvic muscles well. He also has control of his hamstring or flexor muscles. Proceeding below the knee, the first weakness is found in the gastrocnemius, soleus, and posterior tibial. The anterior tibial movement is also impaired. He has a limited defect in the movement of certain muscles of the left foot, the right showing a similar but better condition.

This examination of the patient for motor paralysis shows that the loss which is now present is chiefly dependent upon compression or destruction of the nerves which go from the sacral spinal segments, with very likely also involvement of the nerve-fibres proceeding from the fourth lumbar segment. This conclusion will be confirmed by an examination of the following table of the segmental representation of muscles from the fourth lumbar segment downward:[1]

Fourth lumbar segment: Abductors of thigh, adductors of thigh, flexors of knee, tibialis anticus, peroneus longus.

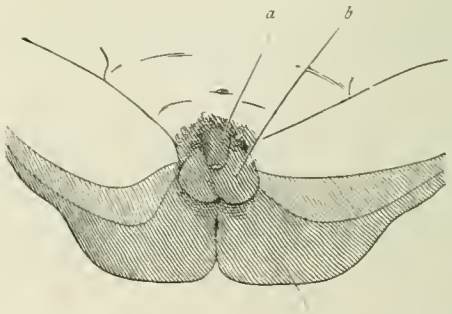
Fifth lumbar segment: Outward rotators, flexors of knee, flexors of ankle, peronei, extensors of toes.

FIG. 1.



a. Small sciatic.
b. Ext. saphenous.
c. Int. long saphenous, branch of ant. crural.

FIG. 2.



a. Dorsal nerve of penis, branch of inf. pudic. Superficial cutan. perineal.
b. Superficial cutaneous perineal, branch of inf. pudic. Inf. pudendal, branch of small sciatic.

First and second sacral segments: Flexors of ankle, extensors of ankle, long flexor of toes, intrinsic foot-muscles.

Third, fourth, and fifth sacral segments: Gluteus maximus, perineal, muscles of the bladder, rectum, and external genitals.

Fifth sacral and coccygeal segments: Coccygeus muscles.

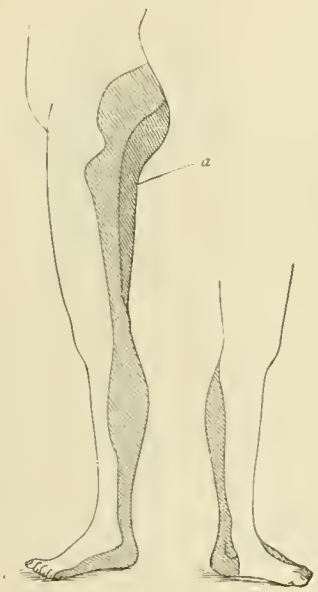
As already indicated, the movements most affected are those about the ankle, particularly extension of the foot, chiefly performed by the gastrocnemius and its

[1] From paper on Spinal Localization, Therapeutic Gazette, May and June, 1889.

associated muscles. Other movements of the toes are weakened. These movements are governed mainly by the sacral segments of the cord. Evidently the nerves which escape from the spinal canal lowest down are the most affected. Thorburn regards it as established that in a pressure lesion of the entire cauda equina, those nerve-roots which emerge lower down are more seriously injured than those above them. In a case of hæmorrhage into the cauda-equinal space, this is what might be expected from the settling of the blood.

Dr. Rosenau, one of the internes of the hospital, who studied these cases carefully with me during his term of service, has made several diagrams of this case which show the areas of loss and defect of sensation. They show back and side views of the patient, and also views of the external genitals, perineum, and adjacent region (Figs. 1, 2, and 3). They show by dark and lighter

Fig. 3.



a. Small sciatic.

shading that in certain areas the loss of sensation was absolute, while in others it was partial, and both the absolute and partial areas of anæsthesia illustrate the distribution of certain sensory nerves which are close together in the cauda equina, almost as clearly as they could by an experiment in which some of these nerves were completely severed, while others were partially cut or compressed.

The following, from my table[1] of the "Localization of the Functions of the Spinal Cord," shows the cutaneous areas, and also the names of the nerves corresponding to the different spinal segments, from the third lumbar downward to the termination of the spinal cord:

Third lumbar segment: Front of thigh. (Middle cutaneous, internal cutaneous, long saphenous, obturator.)

Fourth lumbar segment: Inner side of thigh, leg, and foot. (Internal cutaneous, long saphenous, obturator.)

Fifth lumbar segment: Back and outer side of leg, sole, dorsum of foot. (External popliteal, external saphenous, musculo-cutaneous, plantar.)

First and second sacral segments: Back and outer side of leg, sole, dorsum of foot. (Same as fifth lumbar.)

Third, fourth, and fifth sacral segments: Back of thigh, anus, perineum, external genitals. (Small pudic, inferior hæmorrhoidal, inferior pudendal.)

Fifth sacral and coccygeal segments: Skin about the anus and coccyx. (Coccygeal.)

A study of this table in connection with the examination of this patient, shows the nerves affected to be some of those given off from the fifth lumbar to the coccygeal segment. The area of complete anæsthesia and analgesia is that supplied by the small sciatic, pudic, inferior hæmorrhoidal, and inferior pudendal nerves, which arise from the lower part of the sacral plexus and from the lowest segments of the spinal cord (Figs. 1 and 2). The area of incomplete anæsthesia is mostly in the distribution of the external and long saphenous nerves. Generally speaking, the sensory nerves which escape belong to higher segments of the cord than those which are involved, the exception to this being the partial involvement of the long saphenous which comes from the third and fourth lumbar segments.

It is now pretty generally conceded that the ano-vesical centre in man is situated in the lowest segments of the spinal cord, and this case, and, indeed, the others which I will presently examine before you, confirm this view. The swelling and the blueness of the limbs were vasomotor affections connected with the nerve injuries. The pains which he suffered after the accident were, doubtless, from direct irritation of the nerve trunks by the lesion. This patient shows no external deformity as the result of his injury. If a fracture occurred at all, it must have been without displacement, and, on the whole, the probabilities are that the case is one of hæmorrhage.

Briefly reviewed, we have the history of an injury resulting from a fall from a height with a sudden loss of power in the legs. He had at first little loss of sensation, although after fifteen hours it became much greater than is now present. He had also immediately after the injury great pain in the back, shooting thence down the limbs and toward the pelvis and the perineum. Paralysis, anæsthesia, and shooting pain were then his symptoms, moderate in degree at first, and in fifteen or twenty-four hours increasing in severity, showing that probably the hæmorrhage which occurred at the time of the injury had been followed by an additional flow of blood in a few hours. He also had symptoms showing an involvement of his bladder and rectum—namely, incontinence of urine and fæces. We find no indication of a lesion high up in the cord. As we can pick out the exact sensory and motor nerves affected, we learn the exact height of the lesion in the spinal canal, and the nerves affected in their intra-spinal course.

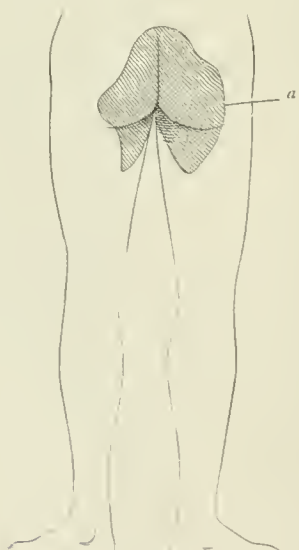
As far as treatment is concerned, on the whole, it was wise to let him alone at first. He had no sign of external injuries. It was probably a purely hæmorrhagic case, and in trephining we would have done so only for a hæmorrhage. It might have been well to have done this, aspirating the blood, and so have prevented degeneration of the nerves from compression; but now it would not be worth while. Possibly if he had been

[1] Op. cit.

trephined, he might have been in a better condition than he now presents, but still a conservative surgeon would probably not have operated in such a case.

CASE II.—*Fractures of the spine and posterior vertebral arch, with probable hæmorrhage into the cauda equina. Sensory and motor symptoms similar to Case I., but less marked.*—T. C., twenty-six years old, while working on a railroad was, with two other men, crushed by a truck loaded with coal being thrown backward upon him. At once he had tingling and numb sensations in his legs, and could not sit nor stand. For about fifteen or twenty minutes he could move his legs, but had loss of power and sensation in them. About four hours after the accident he began to have pain shooting from the sacrum down both legs. He was four months in bed, unable to stand or walk, but gradually recovered power in the legs, and at the end of that time could stand by holding on to a chair; since then he has been gradually getting better. If constipated, he is compelled to remove the fæcal mass mechanically, but if his bowels are loose he has loss of control over them. He uses the catheter, and if he is careful there is no dribbling. When the bladder is full he can pass some urine voluntarily. The dribbling is from overflow, the paralysis appearing to be rather of the bladder walls than of the sphincter. Sexual power and inclination are diminished but not lost.

FIG. 4.



a. Small sciatic.

This case presents features almost identical with those shown by Case I., only the amount of damage to the cauda equina is less, as shown by the narrower area of complete anæsthesia (Fig. 4). No area of imperfect sensation surrounds that of total anæsthesia.

He has little loss of power in his legs, though, as he says, his left leg thumps a little in walking. At first completely paralyzed, he has now only a slight loss of power in his left foot. The little trouble remaining is mainly in his ankle extensors, which are represented low in the sacral segments. We have here then the same sort of lesion as in the other case. He has, however, a very visible deformity on his back, the result of the injury in about the position of the first lumbar spine. He probably suffered a fracture, not of the bodies of the vertebræ, but of one or two posterior arches and spines, which were driven in and somewhat over, thus causing deformity. A hæmorrhage may also have occurred at the same time, and have found its way down into the cauda equina, although this is uncertain. It is possible that this fracture is still allowing bone to press upon the conus or nerves, thus giving rise to the symptoms. Trephining here offers some hope of improvement for his ano-vesical, sexual, and sensory symptoms.

The third case is much more serious in its nature than either of the other two, and trephining should have been performed at once.

CASE III. *Probable fracture of the spine with hæmorrhage into the lumbo-sacral spinal cord and cauda equina; marked anæsthesia in the distribution of the sensory nerves from the fourth lumbar to the coccygeal segments; almost complete paraplegia in the muscles supplied from the third lumbar segment to the extremity of the conus; advanced vaso-motor, trophic, and electric changes.*—K. M., aged sixty, born in Ireland, a domestic, two years ago fell from a shed and injured her spine, immediately losing power in the lower limbs, and having sharp pains radiating round the abdomen. We will not go into a detailed examination of this case, but will give briefly the results of examination. The patient presents complete motor paraplegia of the lower extremities with foot-drop. Knee-jerk is abolished, and sensation much impaired. The bladder and rectum are paralyzed. The skin is glossy. There is sensitiveness to pressure over the upper lumbar spine. Examination shows a large curvature of the back with projection beginning about the sixth dorsal vertebra and reaching to the sacrum. The left side of the back from the sixth dorsal down has a bulging appearance. She complains of tenderness all along the spine below the second dorsal vertebra. It is a question how far the curvature is angular from vertebral disease, and how far muscular due to abnormal positions. She has considerable power to twist and move the trunk in spite of the deformity. She does not present any indication of caries. The limbs are wasted and mottled, and are much colder than they should be. The nails are brittle and show bad nutrition. Faradic and galvanic contractility are abolished in most of the muscles of the lower limbs. Here are diagrams showing her condition as to sensation. (Figs. 5 and 6.)

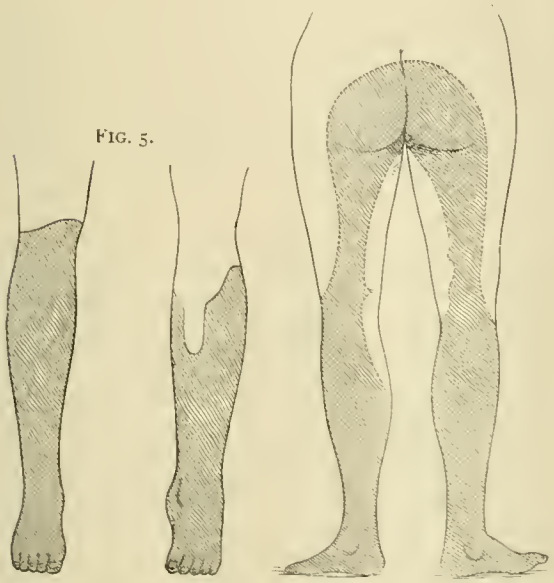
As you see, her legs can only be moved a little above the knee, and not at all below. She has some power in the pelvic muscles. As to sensation, the loss is almost absolute below the knee anteriorly; behind one can pass all the way up the thigh without finding any sensation, provided in the popliteal region we keep within a narrow isthmus. The genitals and the same regions of the buttocks and thighs are anæsthetic, as well as the coccyx and anus, as in the other cases. We have here, then, an involvement of all the motor and sensory sacral nerves, and to some extent those of the lumbar segments, with accompanying vaso-motor, trophic, and electrical changes, the result of a fracture of the spine above the sacral segments over the conus, or of a crushing of the whole lumbo-sacral portion of the spinal cord.

These cases, as already stated, present points of great

interest for diagnosis, both local and general. Thorburn gives injury or disease of the lower part of the cord, extra-spinal nerve disease and injury, and locomotor ataxia as the diseases and conditions from which injury or disease of the cauda equina is to be differentiated.

Fig. 6.

Fig. 5.



If we bear in mind the definite physiological symptoms—the circumscribed cutaneous areas of loss of sensation, the exact muscles and muscular groups paretic or paralyzed, and the peculiar involvement of the bladder, rectum, and genitals, the matter of diagnosis will be greatly simplified. Myelitis must be distinguished by its history, and by the peculiar distribution of the loss of sensation and motion characteristic of that disease This is, however, a difficult diagnosis, if the myelitis attacks the lowest portion of the cord.

Thorburn[1] speaks as follows of the diagnosis from injury or disease of the lower part of the spinal cord: "Here we must be guided by the exact site of the local symptoms, if any be present, remembering that the cord does not extend below the lower border of the first lumbar vertebra. Also, if the cord be there injured, there will probably be some anæsthesia or hyperæsthesia of the last dorsal or first and second lumbar nerves; and again we may expect more rapid trophic lesions than in injuries of the cauda. If the symptoms be asymmetrical, we have probably to do with an affection of the cauda rather than of the cord. Whether in a partial crush above the level of the last dorsal vertebra, the damage down to the anterior crural nerves bears the same relation to that done to the sciatics, as in a crush lower down, I have at present no evidence to determine."

Disease or injury of the nerves or nerve plexuses outside of the spinal canal—lumbar or sacral—might sometimes be confounded with affections of the cauda equina. Thorburn says that the only disease of this kind liable to be mistaken for an affection of the cauda equina is some variety of multiple neuritis, and that we may usually decide the point by finding some affection of the upper limbs, by the marked preference of that disease for the extensor surfaces, and by the slighter sensory symptoms. Some of the affections to which I have called attention in a paper on "Lesions of the Sacral and Lumbar Plexuses,"[1] might occasionally be confused with disease of the cauda equina. These affections are neuritis, neuromata, non-neural growths implicating nerves, caries, abscesses, gunshot and other injuries, and rectal, ovarian, or even uterine disease. Usually these affections are unilateral, and this fact will serve to separate them from lesions of the cauda equina. Bilateral lesions of the sacral plexuses, such as neuritis, paralysis from labor, and tumors in both pelvic cavities sometimes occur. In some of these cases close examination by the rectum will be of great assistance. Unilateral affections of the cauda equina, while conceivable, are exceedingly rare.

It would hardly be thought probable that locomotor ataxia, of which disease our knowledge is now so full, could be confounded with the affections under consideration, and yet within a few weeks I have seen in consultation a patient in whom this mistake was made. This patient was a man between sixty and seventy years of age, a free liver, who sixteen months before coming under my observation had a slight cerebral apoplectiform attack, probably a small hæmorrhage. From this he recovered rapidly. One year later he was taken suddenly with severe pain in the lower part of his back, which lasted for several days, and left him paralyzed, both as to sensation and motion, in both his legs. He also had sharp, shooting pains coming and going in various parts of his legs. He was confined to his bed for nearly three months, all the time slowly improving. His bladder was affected from the first, the urine dribbling nearly all the time. His rectum was also paralyzed. When examined by me his symptoms were very similar to those presented by the patients we have studied this morning. His left leg was almost completely paralyzed below the knee, his muscles showing the reaction of degeneration. The right leg was paretic, all movements being preserved, but nearly all deficient. He had absolute loss of sensation in the distribution of the small sciatic, pudic, inferior hæmorrhoidal, and inferior pudendal nerves, with also loss of sensation below the knees, similar to Case III., although not as complete. He had a sprawling, halting, clumsy gait, somewhat like that of an ataxic, and he complained of feeling as if he was walking or sitting on gum. Several physicians had regarded the case as one of locomotor ataxia. It certainly bore all the marks of a hæmorrhage or tumor of the cauda equina, probably the former, owing to the rapidity with which the symptoms developed. The diagnosis in this case and in others is to be made by a careful consideration of both history and symptoms. The simulation of posterior spinal sclerosis is coarse and not likely to deceive on careful examination. The history of sudden onset, whether following injury or not, would be in favor of an affection of the cauda equina. While locomotor ataxia is sometimes the result of injury, the disease does not develop abruptly. The pains of locomotor ataxia are more irregularly distributed and

[1] Brain, January, 1888, p. 403.

[1] The Medical News, June 15, 1889

have usually gradually increased, both in severity and extent, over a long period. In locomotor ataxia the loss of sensation or the retardation of sensory conduction is usually bilateral and not generally so complete. In lesions of the cauda equina we have, as shown by these cases, clearly defined areas of loss of sensation according to the nerve or nerves involved. Pupillary and other ocular symptoms, gastric crises, and generally symptoms above the waist, are entirely absent. Reaction of degeneration is present in disease of the cauda equina, and close examination shows true paralysis of certain muscles, while the apparent or real incoördination, when present, is the result of defective sensation in the feet. When diseases and injuries of the cauda equina have been brought sufficiently before the profession this mistake will not often be made.

FISSURE OF THE ANUS. CONGENITAL STRICTURE OF THE RECTUM.

A Clinical Lecture
Delivered at the New York Post-Graduate Medical School and Hospital.

BY CHARLES B. KELSEY, M.D.

GENTLEMEN: While waiting for the case with the consideration of which most of the hour will be needed to-day, I will operate upon this typical fissure of the anus. The patient gives the usual history of pain after stool, and an examination shows first a painful cutaneous tag, the size of a pea, at the verge of the anus; and, beginning at the upper limit of this, a granulating ulcer, the size of the finger-nail, running up into the anus.

The usual way of curing this affection is to dilate thoroughly the sphincter. This is radical, but in common charity it demands the administration of an anæsthetic, and conveys to the patient all the horror of an operation. To show you that this is not necessary, I will inject a few drops of cocaine under the ulcer, entering the needle in the skin and passing it forward till its point is at the level of the centre of the sore. After time has elapsed for this to take effect a speculum is introduced, more to show you distinctly the extent of the disease than because it is necessary for the operation, and a sharp knife is drawn longitudinally through the fissure. The external tag is then cut off with the scissors, there is free bleeding for a moment, easily controlled by pressure, the speculum is withdrawn, and the patient given some compound licorice powder to take nightly and told to report day after to-morrow.

In making this incision the only point is to enter the knife above the margin of the ulcer and end the cut below it, taking care to divide those fibres of the external sphincter which form the floor of the fissure. No division of the whole body of the muscle is necessary.

This is an operation any of you may practise in your office; it is free from danger, and it accomplishes, when properly done, all that can be gained by forcible dilatation, the patient being relieved of the characteristic pain of the affection from the moment of the incision.

CONGENITAL STRICTURE OF THE RECTUM.

The next patient, as you will see, is a little boy of four years, seemingly well nourished and presenting nothing unusual in his appearance; and yet when I tell you that, according to the statistics of the largest lying-in asylums, children suffering as he does are only born in the proportion of 1 to 25,000, you will observe him with a good deal of interest. These figures are perhaps as correct as any we are likely to get, but the condition is so rare that any attempt at statistics is apt to be useless.

The child's mother tells us that he has always been constipated, has never been able to have a passage from the bowels without great straining, and when she brought him here three days ago he had had no passage at all for four days. He was also vomiting everything, though this may have been due to the frequent doses of castor oil which had been administered without other effect. The vomiting does not seem to have been stercoraceous, as far as can be judged from the description of the ignorant mother.

We first strip the child and find the abdomen distended, hard, and resonant on percussion, the thoracic viscera crowded upward. There is no accumulation of solid fæces to be made out, nor is such to be looked for in a child of this age. Evidently the patient is suffering from intestinal obstruction in some form, and the most natural thing to do is to make a rectal examination. The anus is found to be perfectly normal, as you see. Oiling the little finger and passing it into the rectum, we meet at one and a half inches an insuperable obstacle. As the child cries and bears down with the fear of the examination, the finger is pressed against by a round, globular mass, seeming to fill the pelvis. As he expires freely the mass disappears, but still the finger cannot be passed any higher than before. Careful search with the tip of the finger reveals a small depression nearer the anterior than the posterior wall of the gut, but the end of the little finger cannot be made to enter it—indeed, can scarcely be sure of its existence, so slight is it. On withdrawing the finger, there is a free jet of fluid fæces for several inches from the anus, showing that even this slight dilatation of the opening, combined with pressure from above, has given escape to this amount of pent-up fæcal matter.

The diagnosis is thus made complete by a simple digital examination, and it is not too much to say that any practitioner treating this child by cathartics without such an examination as you have seen, would be guilty of criminal carelessness.

Before calling attention to the treatment of this case, I wish to dwell a little on its etiology, and the various forms of the affection which may be met.

In early fœtal life the pelvic portion of the primitive intestine terminates in a *cul-de-sac*, in common with the urachus. At about the eighth week the perineum is formed, dividing this cavity into the uro-genital sinus and the anal cavity. In the meantime, and at a much earlier period, a depression has formed in the skin at the site of the anus, which deepens till it encounters the primitive intestine, and union is established between them at about the end of the fourth week. The upper part of the rectum is thus developed from the internal and middle layers of the blastodermic membrane, while the lower is formed by the middle and external layers.

This normal development may be arrested at almost any part, and hence result the different varieties of congenital malformations, not only of the rectum but of the

genito-urinary tract. These may best be studied in the following groups:

1. Narrowing of the anus or rectum without complete occlusion.

To this group our case of to-day belongs. The narrowing may be more or less slight, sometimes causing only little disturbance, or again, as in this case, amounting to almost complete occlusion. This child would have died long since had this narrowing been a little higher up the bowel. As it is, the part of the rectum in which the stricture occurs being low down is comparatively fixed, and when the child brings all its muscular power to bear in effecting a passage, the bowel cannot by bending escape from the direct line of pressure, and more or less relief is the result as long as the fæces are fluid and there is any opening at all.

Where the opening is large enough to admit of a free passage during early life, no symptoms may be caused till the patient reaches maturity. In the only other case of this form of congenital malformation I have seen, the patient was a strong, healthy man of thirty-six, who had been well all his life up to the time he consulted me. He had always been constipated, had never known what it was to have what other men would consider a natural stool; but at about the age of thirty-five he began to find his constipation, and consequent straining, increasing, which led him to consult a physician. This, by the way, is not an unusual history in these cases, for while the youth is growing to adult age the soft parts are elastic and distensible, but when adult life is reached the elasticity begins to decrease, and the fibrous band makes itself more strongly felt as each year passes.

The stricture in this child is not caused by anything resembling a membranous diaphragm growing across the lumen of the bowel. It is nothing that can be cut across as a membrane might be, and which would then shrivel up. On the contrary, the bowel is in the same condition that it would be had a piece of tape been tied tightly around it so as to reduce its calibre to the size of a filiform bougie, and any cutting operation must, to give relief, involve the complete thickness of the rectal wall and reach into the surrounding cellular tissue.

2. In another class of cases the anus is closed by a membrane very strongly resembling the hymen, a membrane which may be absolutely impermeable, or may have one or more small openings allowing the escape of meconium, and so thin that it can be seen to bulge on each inspiration. This is the simplest and most easily detected of all the forms of malformation, and is the most easily cured by a simple crucial incision; but, unfortunately, it is one of the rarest.

3. In the third class of cases there is no anus at all, and the rectum ends in a blind pouch at a greater or less distance from the perineum. These are easy of diagnosis also, but much more difficult to treat than either of those just mentioned; for if the blind pouch of the rectum be near the perineum, it must be reached from there and pulled down to the surface; but if it cannot be so reached, an inguinal colotomy must be done to save the life of the child.

In trying to decide whether the pouch be low enough to be reached from the perineum, a vaginal examination may be of great assistance, as in a female child fluctuation may be detected in this way with one hand over the symphysis and the finger in the vagina, and in a male child the same may be detected with one finger on the perineum. Resonance on percussion of the perineum, and any bulging when the child cries, are also valuable aids to diagnosis. Usually, however, an incision must be made in the perineum and the dissection carried upward for an inch into the pelvis, to decide whether or not the rectal pouch can be reached in this way.

4. In a fourth variety, the rectal pouch is the same as in the last, and the anus the same as in the little patient before us. In other words, instead of there being, as in our case, a constriction of the rectum which is still pervious to a slight degree, there is a complete absence of the rectum for more or less of what should be its course, as though two sections of an aqueduct had been properly built and the intermediate one not commenced.

Except in the cases of greater abnormality, such, for example, as entire absence of the large intestine with a fæcal fistula at the umbilicus, or in the loin or groin, all of the other varieties consist of communications between the rectum and the genito-urinary tract. The rectum either ends in the bladder, vagina, or penis, and discharges its contents through them, or the bladder, uterus, or vagina ends in the rectum, and discharge in this way. Some of these are more serious than others. The rectum may terminate in the vagina, for example, and the child grow to adult life and have children. In the male, also, it may end in a fistulous track in the penis, and the man live to middle age and be the father of a family.

But, on the other hand, when the rectum discharges its contents into the bladder, the little sufferer is usually soon carried off, unless relieved by operation, by the irritation of the resulting cystitis.

Coming now to the question of treatment, the most natural thing to do in the case before us is by some method to enlarge the already existing opening, and try to keep it enlarged. In other words, I shall, if the mother will consent, treat this stricture as I would treat any other non-malignant stricture of the rectum in an adult—first cut it freely open, and then trust to gradual dilatation to preserve the opening. The child should be chloroformed, the anus dilated, the opening found and nicked with a blunt-pointed bistoury till the little finger can be passed through, and the dimensions of the septum made out. If it prove to be thin and easily torn, I shall break it down by forcible divulsion with the finger and, after a couple of weeks, begin the steady use of bougies. If it be found hard, thick, and fibrous, I shall cut entirely through it and through the posterior wall of the bowel into the peri-rectal cellular tissue in front of the sacrum. In this case drainage must also be provided, either by carrying a drainage-tube from the incision into the bowel, out through the skin at the tip of the coccyx, which is the preferable way, or by extending the incision made into the rectal wall downward through the anus and dividing all the soft parts down to the tip of the coccyx. You may ask, why cut so much more than is necessary actually to divide the stricture? Because an incision through the rectal wall into the surrounding cellular tissue at any point, without at the same time providing free, absolutely free, drainage, is about as dangerous an incision as can be made in surgery. It is to open the lymphatics of this region to a constant supply of infective material, and then bathe them in it at all times except immediately after the bowels have been

moved. Even the strictest antisepsis, with free drainage, will not always prevent blood-poisoning in these cases, so what can be expected without drainage?

In the treatment of the other varieties of malformations, I will only mark out a few guiding principles.

Where there is obstruction to any appreciable extent, always operate to relieve the obstruction at once. Many a life has been lost by the surgeon postponing the operation which he admits to be necessary, till he has given a purge to see whether this will not cause a bulging of meconium in the perineum to guide the knife. This is entirely unjustifiable. I came down from the mountains last summer in answer to a telegram to operate upon one of these cases, but when the surgeon in charge found I could not arrive within less than eight hours, he operated without me; and though I regretted not being present, I could not but appreciate how much better the chances were for the child than if he had waited.

Another rule is not to use a favorite instrument with many in these cases—the trocar—plunging it blindly into the pelvis in the hope of finding fluid. Remember that in the newly born the distance from the tip of the coccyx to the promontory of the sacrum is only a trifle over an inch, and that the peritoneum is much nearer the surface than this. The trocar in itself can do no good and may inflict fatal injury. Even should it reach meconium, its track must be followed by an incision, and this can be made with equal certainty without the trocar.

Where the anus is absent, it is a good rule always to search for the rectal *cul-de-sac* first, through the perineum, carrying the incision into the hollow of the sacrum at least an inch from the surface. The pouch may be reached and drawn down and fastened to the surface either at its proper point, or backward at an opening made by amputating the coccyx. If it cannot be reached in this way, an inguinal colotomy should next be done, and a sound passed down the rectum from above as a guide to the operation from below. If it be found possible with this additional guide to complete a communication from the perineum, it may be done; otherwise the perineal opening must be abandoned, and the gut stitched to the surface in the left groin as in ordinary inguinal colotomy.

Where the rectum communicates with the vagina and there is no obstruction, all operative interference may be postponed till the child has grown to adolescence, for the operation of Rizzoli can be much more easily performed then than at birth. This procedure consists, briefly, in transplanting the opening in the vagina with the sphincteric fibres which are usually present, into the perineum and fastening it to the skin at the proper point, closing the vaginal and perineal incisions by sutures.

We will now explain this case to the child's mother, and if she consents to the operation, as it is quite possible she may not do—being, as you see, an ignorant foreigner in the lowest walks of life—we will bring the child into the hospital, and operate before you at our next meeting.

Sodium Salicylate in Pruritus.—Dr. Werthheimer has recently treated three cases of universal pruritus with moderate doses of sodium salicylate, the intense itching disappearing within a few days in each case. The amount of the drug employed was six tablespoonfuls of a three per cent. solution, three times daily.—*Schmidt's Jahrbücher*, January, 1890.

ORIGINAL ARTICLES.

FOUR CASES OF SUPRA-PUBIC CYSTOTOMY, WITH REMARKS.[1]

By ALBERT VANDER VEER, M.D.,
PROFESSOR OF DIDACTIC, ABDOMINAL, AND CLINICAL SURGERY IN THE ALBANY MEDICAL COLLEGE.

At the meeting of the American Surgical Association for the year 1887, a very valuable discussion of the various methods of treating vesical calculus, and the exploration of the bladder, took place. Drs. F. S. Dennis and John H. Packard furnished two exceedingly interesting contributions on supra-pubic cystotomy, and I, myself, looked into that operation with especial interest in relation to its application in the treatment of stone, and bearing upon the paper I then presented.[2] At that time supra-pubic cystotomy was fairly reviewed, and had many eminent and enthusiastic advocates. On the other hand, the operation was very cordially condemned by others. I remember very well the statement of Dr. Agnew: "I have always said that I do not see the advantage of going on top of a house to get in, when an entrance can be had on the ground-floor." About this time Mr. Reginald Harrison had written very forcibly and intelligently on the perineal route to the bladder for the delivery of stone, and drainage for the relief of cystitis with prostatic hypertrophy. Sir Henry Thompson had also just published his monograph on tumors of the bladder, advocating the median perineal incision for their removal. These things, together with the mortality following supra-pubic cystotomy, the fear of urinary infiltration, the vexed question of drainage, etc., led me to adopt the procedure of Mr. Harrison and Sir Henry Thompson in the management of tumors and cystitis requiring drainage. My results were disappointing, and I was satisfied that we must look to supra-pubic cystotomy for more perfect results.

At the meeting of the American Surgical Association of 1888, a paper read by Dr. Hunter McGuire, on "The Formation of an Artificial Urethra in Prostatic Obstruction," made a profound impression upon my mind, and I resolved upon a wider application of the supra-pubic incision.

Case I.—Mr. L. H., aged forty-seven, married, native of the United States, and by occupation a carpenter, entered my service at the Albany Hospital, November 26, 1889. The clinical history is as follows: Father and mother died at an advanced age; whole family very vigorous; an uncle died of cancer, and the patient himself was never strong. When a youth he was thrown from a horse, and sustained a rupture of the left testicle. Since the acci-

[1] Read at the meeting of the Medical Society of the State of New York, February 5, 1890.

[2] To what Extent can we Classify Vesical Calculi for Operation?

dent he had always suffered from local neuralgic pain. After continued treatment, the testicle, which was atrophied, was removed, December, 1885, with complete relief. At this time he had a slight hæmorrhage from the bladder, but continued in good health until the spring of 1887, when there was a return of the hæmaturia, together with vesical tenesmus and retention of urine. This condition did not improve, and he entered the Hospital. December 28, 1887. The urine contained pus, blood, and mucus, but the kidneys seemed free from disease. The exploration of his bladder with a searcher was attended with great difficulties, and could only be accomplished under anæsthesia. An irregular mass could be made out on the left side of the bladder. On January 3, 1888, I operated for the removal of the growth. The incision for median lithotomy was made into the membranous urethra, the neck of the bladder dilated, and a mass the size of a small orange removed by the curette and forceps. The bladder was irrigated with borated solution, a full-sized catheter introduced through the perineal wound for drainage; the patient recovered with the usual after-treatment, and returned to his home. After his discharge he continued the irrigation of the bladder *per urethram*, and for a time was in a fair condition of health. However, during the summer there were slight hæmorrhages, and later his old symptoms returned. I advised that he reënter the Hospital and submit to a supra-pubic cystotomy. November 30, 1888, the operation was done. The incision was somewhat embarrassing, as the abdominal walls were very fat. The digital exploration of the bladder revealed a papillomatous mass as large as an apple on the left anterior wall of the bladder. It was removed with the finger and the curette. Hæmorrhage was very free, but was controlled by irrigation with hot borated solution. A Trendelenberg drainage-tube was introduced, and the lower portion of the wound closed. A siphon was attached to the drainage-tube and carried over the side of the bed into a vessel. An attempt was made to acidulate the urine by free administration of citric acid, thereby producing asepsis. Patient did well. Bladder was freely irrigated through the wound, with comfort to the patient. His appetite was capricious, and he remained in the Hospital for some time. The healing of the wound was somewhat embarrassed by the deposits of phosphates about the edges, with some suppuration. He returned to his home, although a slight cystitis remained, which was relieved by irrigation. He has kept me informed as to his condition, and is now, after fourteen months, free from his old symptoms.

Case II.—Mr. D. S., aged nineteen, single, by occupation a clerk, entered my service at the Albany Hospital, April 26, 1889. Family history and previous health good. In November, 1889, the patient was seized with a chill, pain in the head, back, and pelvis, high fever, and frequent micturition. A severe cystitis followed. The urine was ammoniacal, filled with pus and mucus, and at times contained clots of blood. An attempt at irrigation caused so much distress that it could not be repeated. About this time the patient began to have attacks of vesical spasm requiring much morphine for relief. He could not assume an upright position. In this condition he was brought to the Hospital. Exploration of the bladder, either by sound or cystoscope, was impossible without anæsthesia. I advised supra-pubic cystotomy. The operation was done May 8, 1889. The section revealed a bladder free from stone, but with contracted and thickened walls. The mucous membrane was studded with tubercular masses, many of which had broken down into ulcers. The wound was partially closed with sutures, and a soft-rubber drain introduced. Spasm compelled the immediate removal of the drain. Hypodermic injections of distilled water would at times relieve the pain. Bladder was washed out with borated solution; his appetite improved, he gained in strength, and returned to his home in the country June 22, 1889. His condition did not change materially, although he was able to be about. The sinus did not close, but when the bladder was washed through the urethra the solution and urine came from it. During December he became worse, and died December 30, 1889. No autopsy permitted.

Case III.—Mr. H. D. W., aged forty-seven, entered my service at the Albany Hospital March 7, 1889, with the diagnosis of stone in the bladder. Family history good. Patient had suffered over seven years from repeated attacks of renal colic. After one of these attacks he had severe burning pain in the penis, but at that time I was unable to find a calculus. He had not consulted any one from the time I first sounded him with a view to operation. For the last two years he has suffered severely, and six months ago was compelled to give up his business. His urine now contained pus, blood, and mucus in great quantities. He had had hæmorrhage from the bladder, and lost flesh and strength. I advised supra-pubic cystotomy, which was done March 5, 1889, and a single phosphatic calculus weighing 530 grains was found. Patient left the Hospital, with the wound completely healed, April 8, 1889. His cystitis was cured, and he had already gained in flesh and strength.

Case IV.—Mr. R. M. F., aged sixty five, married, native of Scotland, came to me, in May 1889, with the following history: About a year ago he had passed fine sand with his urine, and suffered greatly from vesical irritability. There was pain in the glans penis, stoppage of the stream, and slight hæmaturia. The searcher at that time employed by the family physician failed to reveal a calculus. He was treated by the usual remedies, and his bladder washed out at intervals by his family physician, Dr. A. T. Van Vranken. Under this management he improved, and was in fair health until March, 1889, when all of his old symptoms returned with increased violence. The urine was ammoniacal, and contained pus, blood, and mucus in large quantities. There was considerable prostatic hypertrophy. The searcher revealed a stone. I advised supra-pubic cystotomy and drainage. The operation was done May 29, 1889, the usual technique being employed. I not only removed one, but five calculi from different pockets of a sacculated bladder. A Trendelenberg drainage-tube was introduced, and the wound

partially closed to secure a sinus from the bladder, after Dr. Hunter McGuire's method. The old gentleman was comfortable after operation, his bladder was washed daily with boric acid solution, and he left the Hospital, June 24, 1889, with the fistula established. His cystitis was greatly improved. The sinus soon healed after leaving the Hospital, and the bladder returned to its normal condition.

While my experience with supra-pubic cystotomy is not sufficiently great to make a personal generalization valuable, yet I feel that a comparison of it with other operations, done by me for similar conditions, might not be amiss. First, I am sure that I am able to explore more thoroughly by the supra-pubic than by the perineal incision. More especially is this true where the patient is fat and has a deep perineum. My first case of supra-pubic cystotomy here reported was for the removal of a papillomatous growth. I had already operated in the case by the perineal method recommended until recently by Sir Henry Thompson. The subsequent history showed that the second operation was much more successful than the first. The facility with which the operation was done the second time thus showed a great improvement over the first. The growth was more accessible, the hæmorrhage more easily controlled, and by the Trendelenberg position, with the use of the electric light and suitable retractors, an inspection of the field of operation was possible. Drainage was satisfactory. In the case of tuberculosis of the bladder, the diagnosis was surrounded by great difficulties. At that time there were no tubercular deposits in the mesentery, testicles, or epididymis. Primary tubercle of the bladder is exceedingly rare. In this case the exploration was necessary to complete diagnosis. I am convinced that the same principles that are involved in the exploration of other organs should be applied to the exploration of the bladder. Again, the experience of surgeons with tuberculosis of the peritoneum has been very satisfactory. Guyon[1] reported two cases of tubercular cystitis treated by supra-pubic cystotomy and the application of iodoform oil to the ulcer. One case was cured two and a half years later. The other was improved, and there was an absence of tuberculosis in both after treatment. From analogy, quite as much of the improvement can be attributed to drainage as to iodoform oil.

The two cases of stone were both accompanied by a severe type of cystitis, and one by prostatic hypertrophy, multiple calculi, and sacculated bladder. Litholapaxy is, in my opinion, absolutely contra-indicated in such cases. Permanent lithotomy has often been done, and calculi lying in sacs near the fundus have been overlooked. I have had so unfortunate an experience. Then, again, I have succeeded better with supra-pubic siphon drainage than with perineal drainage. It is very difficult to maintain an opening through the perineum after median section. Patients tolerate drainage-tubes badly, and their removal is often necessary after a few hours. After median lithotomy, patients begin to pass urine by the urethra often by the third day.

I had a case, not long since, of cystitis from enlarged prostate, in which the perineal section was done for drainage; a day after the operation the drainage-tube, which was a large one, slipped from the wound, and retention of urine occurred. A good deal more distress was caused in introducing it again, than in the same procedure by supra-pubic incision.

REMARKS ON INTERMEDIATE LAPAROTOMY FOR APPENDICITIS IN ITS QUIESCENT STAGE.

By ROBERT F. WEIR, M.D.,
ATTENDING SURGEON TO THE NEW YORK HOSPITAL.

While a marked advance has been made in the pathology and treatment of perforations and gangrene of the appendix vermiformis and the abscesses that result therefrom, yet it may be questioned whether sufficient data exist at the present moment to warrant the use of so severe a recourse as a laparotomy in those cases in which the disease, previously of a threatening form, has returned once more to a period of quiet. In other words, it cannot be considered as settled that surgery is justified in its interference by the removal of an appendix when symptoms of urgency are not present. This seems arrayed against the teaching which has emanated from so able an exponent as Mr. Treves, but he himself has verbally and otherwise stated that the application of this intermediate laparotomy must, of necessity, be an extremely limited one. In truth, both physicians and surgeons see so many cases that recover, even when an operation almost stares one in the face, especially in these subacute cases, that we feel some uncertainty in these instances.

It is only in the actively progressing troubles in the right iliac fossa that surgeons are now in accord as to the necessity of early interference. As one of those who labored to present this conclusion to the profession, I venture, at the present time, to ask that more consideration be given to this point before accepting too hastily the maxim that the "ounce of prevention" theory applies to an appendix which has given rise to sundry previous attacks of pain, and perhaps dangerous tumefaction in the iliac region.

Though our knowledge has embraced the fact that perforative lesions of the appendix are mainly due to hardened fæcal contents or to foreign bodies (?), and that such openings are prone to be followed by gen-

eral or circumscribed suppurative peritonitis, we are still ignorant, in a great measure, of the simpler forms of appendical trouble, such as inflammation pure and simple, or associated after awhile with stenosis of some part of its canal, and also how often such a stenosis will beget trouble by accumulation of retained materials. Furthermore, if such a distention or inflammation takes place, how dangerous is this compared with the perforative form? or, if perforation occurs from the bursting, is it as infectious as the other kind? May not, too, these simpler troubles be at the bottom of the slighter cases that so often are seen by the family medical attendant, and which the surgeon knows personally but little about? I have recently witnessed two laparotomies, and know of two others that have been performed in this city within the past two months for the ablation of an appendix in its quiescent stage, and have been struck by the total absence in each case of any trace of peritoneal changes from the previous attacks of pain, many of which were reported to have been severe. Most of these cases only showed some stenosis of a portion of the appendical lumen, with moderate accumulation of mucus or muco-pus beyond the removed portion. One only had signs of a previous great distention, and in this case a strong adhesion to a neighboring bowel might have explained some of the recurring symptoms. In only one case, I may here remark, in the fourteen times I have had occasion to remove the appendix in acutely progressing abscess, did I find this tube perforated by a retained secretion—in this single instance there were two openings each the size of a broom-straw, and the resulting abscess had been of nearly two weeks' duration in its development.

In one of the foregoing intermediate laparotomies I occupied the position of a consultant, and agreed with those in charge of the case to an operation. Though this resulted fatally, yet the grounds for the decision were potent to those in charge of the case mainly from the fact not only of the recurrence twice of comparatively sharp attacks of iliac pain, etc., but that the conditions of life of the patient caused him to travel extensively and thus often removed him from the continuance of proper surgical observation.

This condition, with the additional one that the attacks of recurrence should be so frequent as to impair the patient's usefulness in life, seems to me the only reason of weight amply to justify the performance, in the quiescent period, of an operation of acknowledged risk even in the most careful hands.

Time, of course, must solve the doubts that assail one's mind in these cases, and it may demonstrate that the delay which I now advocate as preferable is wrong; but in the cases other than in the circumstances just enumerated it is wiser, in my judgment, to wait until an attack is presented, and which in itself would warrant surgical interference, and which then is to be promptly afforded.

Within the past month I have given this opinion in favor of delay in three cases of recurrent appendical pain, and so far not one has had a return of the symptoms. Mr. Baker, of London, reported himself as the subject of twelve different attacks, and with a final period of freedom from symptoms for over ten years. It is probable, I may admit, that in such a case, seen by me during an attack, an operation would have been advised. But my point is, that only in exceptional and somewhat rare cases is it necessary to "climb the hill before we come to it."

I beg to add to these brief remarks that the significance of pain on the finger-tip pressure, spoken of by Dr. McBurney, between the anterior spine and the umbilicus is somewhat negatived by the investigations of Schüller, who found that the end of the cæcum, and consequently the beginning of the appendix, is situated on the average in a line running from the middle of Poupart's ligament to the umbilicus, at the junction of its middle and lower thirds. Furthermore, I have myself found, on examination of eighteen healthy persons by the above test of McBurney, that in four of them decided evidence of tenderness existed without other history of appendical attacks.

CLINICAL MEMORANDA.

SURGICAL.

Successful Laparotomy for Contusion of the Intestines.—E. A., aged twelve, a healthy farmer's boy, of spare build and nervous temperament, was kicked in the abdomen by an unshod horse, about 4 P.M., August 19, 1889. He cried out as he received the blow, sat down and bent himself forward with his hands over the abdomen. He became pale and faint, objected to being taken into the house, as he preferred the open air, and he vomited freely several times. Liniments and hot applications were used on the abdomen. I saw the patient at 10 P. M., six hours after the injury was received. His pulse was then 120, temperature 99½°; abdomen rigid, but not distended. A red semilunar mark, one inch below the umbilicus and in the middle line, showed the point of impact. Abdomen very tender and the boy was very restless, pale and suffering considerable pain. I gave opiates and applied cold compresses to the abdomen. He vomited again and the opiates were repeated during the night. At my next visit at 8 o'clock on the following morning he was sleeping lightly. Pulse 120, temperature 100½.° Abdomen very tender and decidedly tympanitic, countenance pale and anxious. He had urinated freely twice during the night; urine normal. I ordered sal rochelle every two hours and the cold applications being agreeable, were continued. The salt was given at regular intervals during the day; enemas were

also used, but only resulted in emptying the rectum. At 10 P. M. pulse 120, temperature 101°. Abdomen largely distended, no opiates since 6 A. M., restless, but no severe pain, no action of bowels. During the following night he vomited several times, the vomited matter having a very distinct odor of decomposition. There was mild delirium and the stomach became intolerant of everything ingested.

On the morning of the third day there was a sudden fall of the temperature to 97°, while the pulse ran up to 140 and became very weak. The abdomen was enormously distended, tympanitic above, and dull below the umbilicus; countenance pinched, pale, and anxious. He had had no movement of the bowels since the accident. He tossed from side to side, and moaned, but said that he had no pain.

The sudden fall of temperature below normal, the increasing rapidity and weakening of the pulse, with the cessation of pain, he having had no opiates for twenty-four hours, led me to fear that gangrene of the intestines had occurred. I gave a very unfavorable prognosis, and suggested an exploration of the abdomen, intending to resect the gangrenous portion of intestine, if such a condition existed to a limited extent.

Being strongly impressed with the hopelessness of the case, the parents readily assented to the operation, if I thought it offered any chance whatever for his recovery.

Being in the country, eight miles from home, I left the patient to make the necessary preparations, and get assistance. Having had some experience in abdominal surgery, I had instruments already prepared for that kind of work, and returned in three hours, Drs. Kimball and Eady with me to assist. These gentlemen carefully examined the patient, and gave their unqualified opinion that a fatal termination was to be speedily expected. The patient being anæsthetized, the abdomen was cleansed and surrounded with aseptic towels. My instruments were in hot carbolized water. Hands were scrubbed with nail brush and soap in water as hot as could be borne. My assistants as well as myself, had on aseptic operating robes. The operating room had an oil cloth carpet, which had been mopped while I was making preparation. All water used was boiled, strained, and used as hot as possible. The house and family were cleanly, and all the surroundings were favorable.

The integument still showed the mark where he received the blow. A greenish serum escaped from the rectus as I opened its sheath, the muscle being œdematous and discolored. The abdomen contained considerable inodorous, bloody serum. The intestines were inflated, very red, and presented a sodden, œdematous appearance, and were covered with organized lymph, which also extended across the folds in bands. The omentum was also covered with lymph, in the midst of which was a black spot three-fourths of an inch in diameter. I turned out the ileum and searched for gangrenous intestines, but found none. They were freed from the lymph, and being so inflated that their return into the abdomen would be difficult, I tapped with a trocar, drew off much gas and over a pint of liquid contents. The perforation was closed with a catgut, Lembert stitch, the serum absorbed with a sponge, and the abdominal incision closed with silk sutures, leaving a drainage tube in the lower angle of the wound, which was dusted with iodoform, covered with rubber protective, bichloride gauze, and the usual abdominal bandage. As the serum was inodorous, I did not irrigate the peritoneal cavity. At the close of the operation, as his pulse was 150 and very weak, hot whiskey was given per rectum. He rallied slowly but steadily. He received $\frac{1}{4}$ grain of morphine and $\frac{1}{150}$ grain of atropine, hypodermically, two hours after the operation, on account of the severe burning pain in the wound of operation which caused much restlessness. This promptly rendered him quiet and comfortable. Six hours after operation his pulse was 140, temperature 100°. He became restless during the following night and again received morphine and atropine, which was the last opiate in any form that he required or received. He was also given soluble beef per rectum. The following morning his pulse was 120, temperature 99°. A small amount of serum escaped from the drainage tube during the day. He was given five grains of salol with ten grains of powdered charcoal every three hours; the salol as an intestinal antiseptic, the charcoal as an absorbent, and for another purpose which will appear further on. His kidneys secreted freely and bowels moved spontaneously the third day, the movements being aided by the beef enemas, which he would retain two or three hours. The tympanites subsided, and on the fourth day the charcoal appeared in the fæces, which gave assurance that the intestinal tract was open throughout its entire length, and that constriction from adhesions was no longer to be feared. The drainage tube was removed the third day, and the sutures the fifth, primary adhesion being secured except at the lower end of the incision. Small abscesses formed around two of the sutures where they passed through the contused muscle. They did not communicate with the adominal cavity and were thoroughly evacuated and injected with "campho-phenique," and two days thereafter there was no sign of suppuration.

After the appearance of the charcoal in the fæces, he was given liquid food per orem and the enemas were discontinued.

On the ninth day his bowels failed to move and in consequence became much distended with gas. The tension became so great that in spite of adhesive straps, the wound opened for two-thirds of its length. This gap was in the integument only; the underlying tissues remaining firmly united. The bowels were opened with a saline which relieved the distention. The wound was dressed with gauze wet with "campho-phenique" and granulated without suppuration.

On the fifteenth day I gave an anæsthetic, freshened the edges of the separated integument, and united it with continuous catgut, supported by three silk sutures. The latter were removed five days later, the catgut remaining undisturbed. Prompt closure of the wound was thus secured and no further trouble was experienced. Otherwise his improvement was continuous from the date of the operation, and his recovery was complete.

I am not aware of any precedent for the measures adopted in this case. Accidents from the same cause frequently occur, and quite frequently terminate fatally. The abdominal walls are often but slightly injured, or even marked, owing to their resiliency, and to the protec-

tion afforded by the clothing, and no definite opinion can be formed from the external marks, of the injury which the viscera may have sustained. More or less shock is expected to accompany such injuries, which may deepen into collapse, or be followed by reaction, with subsequent pain, tenderness, distention, constipation, and peritonitis, or other symptoms depending upon the organ injured, or on the nature of the injury received. However, these symptoms are by no means constant, and many cases are on record in which there was but little shock, several days elapsing before collapse indicated that a fatal termination was near, the autopsy revealing rupture of intestines or other extensive lesions.

The general plan of treatment for such injuries has heretofore been rest, opiates, and fomentations, hot or cold. Beyond this it has been wholly expectant, meeting indications as they arose. Authorities have but little to recommend as to surgical treatment where there is no external wound communicating with the abdominal cavity, and where rupture of internal viscera is not certainly known to have occurred. Emergencies frequently occur in the practice of every surgeon, in which he will search in vain for a guiding precedent, but will have to be guided by general principles and devise measures for the relief of the trouble. In this case, expectancy failed, collapse was imminent, and opening the abdomen would scarcely add to the gravity of the case.

The condition of the omentum showed that the attempt at organization of the exuded lymph had been arrested, and its death was occurring. The sodden, œdematous intestines, were inert and any attempt to excite peristalsis by the use of cathartics would be impossible and their exhibition useless. Their paralyzed condition was particularly well shown when I attempted to draw off their contents with the trocar. After the escape of the gas and fluid in the immediate vicinity of the perforation, to get any further flow, manipulation of the gut between the fingers was necessary. The contents could not be forced any distance, but would be arrested by the first bend or flexure of the bowel. Nor do I believe that aspiration would have given any better results.

E. H. King, M.D.

West Liberty, Iowa.

HOSPITAL NOTES.

SYPHILIS. SCABIES. ECZEMA.

Abstract of a Clinical Lecture
Delivered at the New York Post-Graduate School.

By ROBERT W. TAYLOR, M.D.,
PROFESSOR OF DERMATOLOGY.

The first patient presented to the class was a man, twenty-four years of age, who, five years before, had gonorrhœa and several chancres; but he gave no distinct history of syphilis until two months ago, when glandular enlargement and an eruption made their appearance; and subsequently he began to be troubled with rheumatic pains in the knees. As it is the exception to find multiple hard chancres, it is probable that five years ago he only had gonorrhœa and chancroids. At present there is a typical pustular syphilide of the scalp, and a general papulo-pustular eruption, which is pinkish on the legs rather than coppery in color, owing to considerable inflammation.

In hunting for an initial lesion, it is important to examine the lymphatics, and at first sight it would seem that the disease in this case must have gained entrance on the chin; but the glands here are not much enlarged, and this enlargement appeared with the rash. The lesion in this locality has not the depth and consistency of a hard chancre. In all probability the point of entry of the disease was some insignificant lesion on the penis.

No scratch-marks are observed on the legs, and yet the patient complains of itching both of the scalp and legs. As a rule, syphilitic eruptions do not itch, except about the head—where it is common—and it may be remembered that patients saying that an eruption itches, is not sufficient to classify it as a pruriginous eruption; for, it is natural for anyone to scratch a pimple, and after it has been irritated in this way it is quite possible for itching to exist almost entirely as a subjective symptom. These syphilitic eruptions are not pruriginous in the sense that an eczema is a pruriginous eruption. On the legs, the itching is very often due to some temporary acceleration of the circulation in these parts, brought about, perhaps, by wearing flannel or tight-fitting boots, or by a plethoric condition of the system from one's diet, or the ingestion of malt and alcoholic drinks.

The rheumatic pains of which the patient has spoken, depend upon a low grade of inflammation of the fibrous tissues about the joints.

This man has been attempting too much work, and that, too, in the most critical period of his syphilis. In the treatment of this case it is to be remembered that a man thus debilitated can only do about sixty-six per cent. of the work of a healthy man. The diet must be carefully regulated, drinking and smoking carefully avoided, and the patient placed under the best hygienic surroundings. Internally, he should take one-third of a grain of the proto-iodide of mercury three times daily; and locally, he should be instructed to rub a twenty per cent. oleate of mercury ointment into the scalp after proper shampooing. Besides this, it is to be rubbed over the patches on the body, and especially about the knees, and a plaster of the same or of mercurial ointment can be applied at bedtime about these painful joints.

The second case presents an exception to the rule just mentioned, for he has three hard chancres which appeared four months ago. At present there is inguinal adenitis on both sides, and right epitrochlear enlargement, together with a general roseolous syphilide.

In treating this case the spots on the face and hands should be rubbed with a calomel ointment—one drachm to one ounce. It is ever to be borne in mind that in the majority of these cases there are cachexia and debility, and the tendency of the disease is toward depression. In curing the diathesis one must endeavor in every possible way to fortify the system. This man requires a tonic of iron and quinine with one-quarter of a grain of the proto-iodide of mercury, three times daily.

The third case had his chancre two months ago. This was followed by inguinal adenitis; and at present he shows, particularly about the hands and wrists, a larger form of miliary papular syphilide, which has been made itchy by attrition.

Noticing the aggregated papules only about the wrists, one might be led to make a diagnosis of scabies; but on the back of the hand they are not at all inflammatory, and they are entirely absent between the fingers.

This *large* pox bears a certain resemblance to smallpox. The eruption has a hard, shot-like feeling, and on the face looks like a mild case of smallpox; but the patient has not had the prodromal fever, pain in the back, and general prostration which accompany smallpox; and the eruption, instead of coming out on the face, and spreading regularly downward in the course of a week or ten days, has taken at least one month in its downward course; and in doing this it has skipped certain portions, and is centred upon the hands. His occupation, necessitating working in oil, will probably account for the latter fact. In this case only a few of the lesions will go on to the formation of pustules, whereas in smallpox pustulation takes place rapidly. Thus, it is seen, on comparing the symptoms of syphilis and smallpox, that there is a similarity in the lesions only, not in their development, nor in their subsequent career.

In this case a modified treatment is necessary. It must be borne in mind that all these papules on the body are foci of infection; for the syphilitic process in each nodule is capable of causing indefinite multiplication of the new cells. A mild inunction treatment will accomplish much for this patient. Preparatory to the inunction, the patient will bathe his face well with soap and water at night, and then immerse himself for ten or fifteen minutes in a warm bath containing one pound of sal soda to thirty gallons of water. This bath will put the skin and follicular openings in proper condition for receiving the mercurial inunction. The inunction is to be made three times daily with twenty grains of a fifty per cent. blue ointment, beginning at the head, rubbing it in thoroughly, especially around the ganglia, then passing successively to the groins, sides, and legs. Internally, he will be given the citrate of iron and quinine, and will be told to avoid smoking, drinking, and everything which will be likely to disturb the stomach.

The fourth patient says that his syphilis began about sixteen months ago, when he had one chancre, which was followed by an eruption about the shoulders. Dr. Taylor called attention to the fact that in the four cases of syphilis which had been presented, only one had multiple hard chancres. The inguinal glands are somewhat enlarged, though the patient has been under treatment. About ten months after contracting the disease, ptosis developed; but at no time was there any impairment of vision. Ptosis occurring suddenly in young people is very often found to be due to syphilis, and it is a symptom of much diagnostic importance, particularly when combined with mydriasis, which is a not uncommon coincidence.

The patient's general condition is good, and his appetite is excellent, but the eruption has returned. This case at the beginning required very different treatment from that which is now indicated. At present there is nothing urgent; there is simply a relapse of the eruption; but it shows that the diathesis is still active in his system. There is no necessity for tonics, for the patient's appearance shows that he is decidedly robust. He has been well treated, and his nutrition has improved since the onset of the disease. The significant point in this case is that, even though in such a good condition, there has been a relapse of a large pustular syphilide, showing that the infectious material is still circulating through the system.

For this patient, frictions with fifty per cent. blue ointment are recommended for five nights; it should then be omitted for three nights, when the treatment may be resumed for five nights more. Always insist upon the preparatory bath and a thorough cleansing of the parts.

Whatever the treatment, one must always remember to make peace with the mouth, and see that the gums, tongue, and throat are as nearly as possible healthy. When mercurials are being administered, always insist upon the avoidance of smoking and drinking, and of the eating of vegetables and fruits which are apt to produce diarrhœa, particularly in cases where inunctions are employed; for these inunctions may cause colitis. This irritation of the alimentary canal is often sudden and furious in its onset, and is due to some sympathetic or metastatic effect upon the head of the colon. If, during treatment, the patient loses flesh or the digestion becomes impaired, stop the treatment or, if absolutely necessary to continue the administration of mercury, resort to some other method of giving it.

Dr. Taylor next directed the attention of the class to a boy, aged twenty years, who had a mild eruption of scabies, which had begun between the fingers and had spread, by scratching, to the body. The eruption often spreads up the back of the hand, and turns in the furrow at the end of the styloid process of the radius, and then up the arm, centring in the thick skin of the elbow. In this case, the papules along the anterior fold of the axilla have become accompanied by pigmentation from scratching, and all over the body they are small and not very inflammatory. None have appeared upon the penis. Twenty years ago scabies was really rarer than lupus, but now it is quite common. The acarus is transferred by the nails to different parts of the body. It also in its wanderings invades new tissue.

The source of contagion in the present instance is not known, for the patient has not been around horses or dogs, nor has he slept in bed with other persons having itching eruptions, nor has he worn gloves or clothes belonging to others. Dr. Taylor has found that the cases occurring among the better classes, which are far from uncommon, could be traced to a night in a sleeping-car in very many instances.

In private practice, one is doing well if he succeeds in curing his patient within a week. The patient is to soak himself thoroughly in a bath at 100° F., in which there has been dissolved one pound of washing soda, and while in the bath he is to rub himself thoroughly with some good soap that makes an abundant lather, like Pears' unscented soap. Having dried the surface, he is to rub in an ointment, consisting of one drachm each of balsam of Peru and milk of sulphur to each ounce of vaseline. This is to be left on all night. He should have ready clean bedding and clothes.

There is no necessity for internal treatment, but drinking liquor of any kind should be avoided, as the consequent increase in the circulation would add to the irritability of the skin. It is also wise to avoid eating anything which might produce an erythema.

The next patient, a girl twenty-two years of age, and unmarried, presents an eruption which began as a scaly patch on the face, and which was scratched and freely

washed with soap and water. It has spread by scratching to the hands, and has attacked the finger-nails, transforming the skin into rough, harsh, scaly patches—in other words, it is a case of thickened and infiltrated eczema of the neck and hands.

She also has a large furuncle on the arm, and it is worthy of note that these furuncles very commonly make their appearance as the eczematous eruption is declining, or after its disappearance; and it is probable that in the highly sensitive state of the skin associated with this condition, pyogenic bacteria lodge in the follicles and give rise to these spots of suppurative inflammation.

The patient must first be made to understand that all sources of irritation must be removed, that wetting of the hands is to be carefully avoided, and even movement of the parts is to be reduced to a minimum. Internally, she may take an alkaline tonic like the following:

R.—Potassii citrat. . . . . f℥j.
Ferri et quin. cit. . . . . f℥iss
Syrupi . . . . . f℥ij
Aquæ . . . . . f℥viij.—M.

Sig.—One tablespoonful three times daily in two tablespoonfuls of water.

Locally, there should be constantly applied to the affected parts an ointment composed of equal parts of diachylon and zinc ointment, with twenty grains of carbolic acid to each ounce.

The alkaline tonic has a decidedly beneficial effect in allaying the irritability of the skin, and at the same time it improves the general nutrition.

MEDICAL PROGRESS.

The Prevention of Chilblains.—Liebrich recommends the following wash as a prophylactic against chilblains:

R.—Alum, Sodium borate } of each . 75 grains.
Rose water . . . . 9 ounces.—M.

This should be used frequently.

He also advises either of the following ointments:

R.—Sodium borate . . . 80 grains.
Simple cerate . . . 1 ounce.—M.

or,

R.—Camphorated oil . . . 2 drachms.
Lanolin . . . . . 3 ounces.—M.

Hæmorrhage after Tonsillotomy.—According to Sir Morell Mackenzie, hæmorrhage after excision of the tonsils can be controlled by a mixture of tannic and gallic acids better than by any other means. They should be combined in the proportion of one-third gallic acid to two-thirds tannic acid, the efficiency of the combination depending upon the fact that the tannic prevents the gallic acid from dissolving.—*Indian Medical Gazette*, December, 1889.

Iodine in Vomiting.—According to the *Practitioner* for February, 1890, M. Darthier has recently added his testimony to the value of iodine for the relief of vomiting. The drug has been employed for this purpose for years both in America and England. (See *Amer. Journ. of Med. Sci.*, April, 1883.) Darthier has used the tincture in nineteen cases, eleven of which were tubercular subjects, and has concluded that it is of more value in the vomiting of early phthisis than in the later stages of the disease. He relates cases with obstinate vomiting where the symptom was well controlled by the drug. One case had vomited after each meal for three weeks. From the commencement of the iodine treatment vomiting decreased, and at the end of a week had entirely ceased. The drug also proved useful in cases of alcoholic gastritis, gastric ulcer, and in the vomiting of pregnancy and chlorosis.

In the *Lancet* of February 1, 1890, Dr. Frederic Taylor also warmly recommends this method of treatment. He usually administers three to five minims of the tincture well diluted with water, and repeated every hour or half hour for six to eight hours if necessary; the result is usually attained, however, after the second or third dose. He has used it with success in the vomiting of Bright's disease, in cerebral vomiting, in the vomiting of migrain, in vomiting after chloroform, and in that due to gastric disease. In his experience it more frequently relieves than any other drug used for the same purpose.

Tobacco and Alcohol Headaches.—The following prescription for use after excessive indulgence in alcohol or tobacco, is quoted by the *Kansas City Medical Record*:

R.—Aromatic spirit of ammonia ½ drachm.
Spirit of chloroform . . 10 minims.
Water . . . . . 1 ounce.—M.

To be taken in one dose.

Treatment of Acute Gastric Catarrh.—In the treatment of acute catarrh of the stomach, Dr. Saundby, of Birmingham, advises, in addition to a restricted diet, one grain of calomel at bedtime, and before each meal a powder composed as follows:

R.—Bismuth carbonate, Sodium bicarbonate } of each 2 grains.
Powdered rhubarb . . . ½ grain.
Aromatic powder . . . 1 " —M.

If pain is persistent a mustard plaster is to be used. If the patient is subject to recurring attacks, a broad flannel band should be worn around the abdomen.—*Provincial Medical Journal*, February 1, 1890.

The Treatment of Pharyngeal Inflammations by the Administration of Salol.—In a recent number of the *Annales des Maladies de l'Oreille, du Larynx, du Nez, et de Pharynx*, Dr. Gouguenheim reports twenty-two cases of inflammation of the soft palate, of tonsillitis, simple pharyngitis, and other forms of pharyngitis, treated with the most remarkable success by the internal administration of salol in doses of from 45 to 60 grains daily in three separate doses. Dr. Gouguenheim acknowledges his indebtedness to Dr. Caport, of Brussels, who first called his attention to the remarkable value of this remedy in the treatment of suppurative tonsillitis, and on this account was led to test its value in various forms of angina. On account of insolubility, the remedy was simply sus-

pended in a mucilage, with directions given to shake it well before using. The diet was almost exclusively restricted to milk. In all Dr. Gouguenheim's cases there was the most remarkable rapidity observed in the cure of dysphagia, no matter what might have been the cause of the angina; in four cases of severe scarlet fever the same effects were noted. In suppurative tonsillitis, although the results were evident enough to be highly satisfactory, the effects were not as striking as in simple inflammatory affections, though even here the author claims that his success surpasses what was to be expected from any other form of treatment. In some cases the daily dose of 60 grains was exceeded, 90 grains being given in one case where the angina had been complicated by articular rheumatism. In most of the cases there was marked reduction of temperature, with reduction in the swelling of the throat, fever, and dysphagia. —*Therapeutic Gazette*, February 15, 1890.

Strophanthus in Infantile Diseases.—According to the Paris correspondent of the *British Medical Journal*, M. Moncorvo has treated many infantile diseases with strophanthus, and comes to the following conclusions: As a diuretic and for combating cardiac disturbance strophanthus is invaluable in infantile therapeutics. Its action is prompt and energetic. It is perfectly innocuous. The tincture in mitral or aortic lesions with irregularity and deficient secretion of urine restores cardiac tone, regulates the rhythm, and strengthens the pulse. In infantile pneumonia or broncho-pulmonary affections, accompanied by cardiac weakness, strophanthus is a valuable heart tonic. M. Moncorvo has not observed any marked influence on the nervous system or temperature. The action of strophanthus persists long after the treatment has been discontinued. M. Moncorvo employed an alcoholic tincture, in doses varying from four to twenty-eight drops in twenty-four hours.

Corrosive Sublimate for Granular Lids.—In the *Annales d'Oculistique*, Dr. Arnauts reports excellent results in the treatment of granular lids by the application of solutions of corrosive sublimate of a strength somewhat greater than is usually employed. He prescribed collyria of corrosive sublimate in the proportion of 1 to 500 and 1 to 400, and of this one or two drops are instilled into the eyes two or three times daily. He admits that solutions having this strength excite some transient irritation of the conjunctiva; but this disappears in the course of a few minutes, and may be prevented by the antecedent instillation of a few drops of a solution of cocaine hydrochlorate. The remedy, he observes, costs little, and admits of easy application; and reduction of the granulations soon takes place. The effects of the solution are also well marked in causing the vascularization of the cornea to disappear. The same plan of treatment can also be adopted with advantage in cases of ulcers of the cornea, many of which will rapidly heal under the influence of the solution. Dr. Arnauts records several cases showing the advantages to be derived from its use.—*Practitioner*, February, 1890.

Biniodide of Mercury in the Treatment of Scarlet Fever.—In the *Provincial Medical Journal*, January, 1890, Dr. Illingworth records five cases of scarlet fever treated by the biniodide of mercury, in which the disease was aborted in each case in seven days. As soon as the rash was well marked, the following mixture was given:

R.—Solution of bichloride of mercury (Br. Ph.)	6 drachms.
Potassium iodide	15 grains.
Aromatic spirit of ammonia	1 drachm.
Syrup	1 "
Water	6 drachms.—M.

One teaspoonful of this was administered every two hours.

The throat was sprayed every four hours with 1 : 2000 biniodide in sodic iodide. On the seventh day of the disease, in a child nine years old, the rash had quite gone, the temperature was normal, and the tonsils were granulating. In three other cases the same treatment was used with a similar result. In one the throat was not sprayed, and the disease caused otitis by extension along the Eustachian tube. The only case of cervical abscess was one in which no local application was made. In one case urgent purging came on within twenty-four hours, so the mixture was stopped, and the tincture of chloride of iron given every two hours with a powder of one-sixteenth of a grain of the biniodide three times a day. As regards infection, the author states he has since found that by painting the throat with 1 : 500 solution every four hours the disease is prevented from spreading; desquamation is merely scurfy, and chiefly confined to fingers and toes.

Intra-venous Injections of Quinine in Malaria.—Baccelli, of Rome (*Revue Générale de Clinique et de Thérapeutique*, January 23, 1890), in considering the treatment of the graver forms of malaria, advocates the intra-venous injection of quinine, as the drug is absorbed somewhat slowly after subcutaneous injection, and still more slowly when administered by the stomach. Baccelli was the first to experiment with the intra-venous method (*Medical News*, January 25, 1890), and he states that after the intra-venous injection, examination of the blood shows that the hæmatozoa retain their form and activity for from six to twelve hours, when they disappear. Ten minutes after the injection the drug appears in the urine. The solution used by Baccelli consists of hydrochlorate of quinine, 15 grains; chloride of sodium, 1½ grains; distilled water, 2½ drachms. The operation is conducted with strict antiseptic precautions, disinfecting the skin with sublimate solution. A band, as for venesection, is placed around the arm, and the needle is then carefully inserted into the most prominent vein, and the solution slowly injected. Not more than from seven to twelve grains of the quinine salt should be used for one injection, as larger doses produce symptoms of cinchonism. It is useless to give the quinine during a paroxysm, the proper time being after the paroxysm is over. Given at such a time, it will prevent, or greatly modify the subsequent attack. In remittent malarial fever, the injection should be made at the beginning of the remission.

Treatment of Epilepsy with the Actual Cautery.—In the *Revue Générale de Clinique et de Thérapeutique*, Jan. 23, 1890, Dr. Descroizilles reports three cases of epilepsy treated with the actual cautery. The first was a

boy of eight years, suffering from *petit mal*, with many attacks each day, and an occasional true epileptic convulsion.

The second patient, a boy of four years, had suffered from *petit mal* since the first month of his life, the attacks later becoming convulsive.

The third case, aged nine years, gave a history similar to the preceding, except that the attacks were less frequent.

All of these cases Descroizilles treated by means of cauterizations of the shaven scalp with a point of hot iron. In the first cases, ten successive cauterizations were made in a period of six weeks; in the second, six; and in the third, four cauterizations; each application consisting of about thirty light touches with the heated point. None of the patients resisted the treatment, nor was it followed by pain or inflammation. In the first patient the attacks were reduced to one or two a day, then ceased for several days, but finally returned with their former severity.

In the second case, improvement followed for a few days, but was only temporary. In the third case, no influence on the disease was exerted by the treatment.

Antiseptic After-treatment of Vaccination.—Mr. John Bark, of Liverpool, after a long experience as public vaccinator, finds that there is not inconsiderable danger of erysipelas after vaccination, particularly among the poorer and dirty classes. This danger, he believes can be avoided by dressing the arm with a large pad of borated or eucalyptol cotton after opening the vesicle on the eighth day. On removing this pad, six or seven days after its application, it is found that the inflammatory infiltration has entirely disappeared, and in most cases a firm, hard crust has replaced the vesicles, so that the arm can be left unprotected.

The Treatment of Asthma.—Dr. T. F. Pearse writes, in the *Lancet*, February 1, 1890, that in the treatment of asthma nothing is equal to sodium nitrite. As a rule, he prescribes it alone. In some cases, however, with the object of promoting sleep, he combines hyoscyamus with it. In other cases, the addition of tincture of lobelia has seemed of benefit. When the sodium nitrite first came into use, he gave several doses of ten or fifteen grains to one patient who had suffered from repeated attacks of uncomplicated asthma for several years. The first dose made the patient so sick and faint that she could hardly be induced to repeat it, but she was freed from her asthmatic attacks up to the present time, a period of two or three years. Since then he has given it in doses of from three to five grains, frequently repeated, and always with the greatest benefit. With regard to hyoscyamus in asthma, he has found that the ordinary doses are of little use. Two drachms of the tincture are prescribed for a single dose, or one drachm, if it is to be repeated. Given alone in asthma, it will not relieve the paroxysm, but, combined with sodium nitrite, the effects are sometimes marvellous.

Treatment of Buboes.—In the Lyon *Médical* for January 26, 1890, M. Cordier contributes an article on the treatment of bubo, in which he describes the various methods which are best adapted to the treatment of this troublesome condition, and reaches the following conclusions: First, in all cases puncture of the inflamed gland is to be performed, and the risk of meeting with pus is to be taken. Second, after the puncture, it is best to make an injection of a solution of nitrate of silver of the strength of 1 to 50. This he believes to be productive of a very rapid cure with a healthy cicatrix, although the method is more active than those generally employed.

The Disadvantages of Sulphonal.—According to Henocque, sulphonal produces profound sleep, does not diminish reflex action, and is not an analgesic. A sufficiently large dose causes, in animals, death from arrested metabolism and depression of temperature. Its unquestionable hypnotic properties have been used by many alienists, who prefer it to chloral, paraldehyde, hypnone, or amylene hydrate. Italian and German physicians are particularly enthusiastic, the French less so. The latter have found it an unfaithful hypnotic in doses of fifteen to twenty grains, and that in larger amounts it causes chilliness, vomiting, diarrhœa, cutaneous eruptions, stupor or vertigo. Melancholics complain of hallucinations after its administration; hypochondriacs are depressed. —*Revue Générale de Clinique et de Thérapeutique*, January 23, 1890.

Sunflower in the Treatment of Malaria.—In the Moscow *Meditzinskoïeee Obozrenië*, Dr. Maminoff writes that he has recently tried the sunflower in ten successive cases of malarial fever in children aged from one to eleven years. Some of the cases were of an extremely severe and refractory nature, the affection having persisted in spite of treatment by quinine, arsenic, ergot, calomel, etc. In each of the patients, the sunflower course was rapidly followed by radical cure; in recent cases, the paroxysms ceased to recur from the second day of the treatment; in more inveterate ones, from the fourth or fifth. The remedy was employed in the shape of a tincture (1 : 5), prepared of fresh flowers and bark of the plant, the dose varying, according to the patient's age, from ten to twenty-five drops three or four times daily. Since the tincture is free from any pronounced or unpleasant taste and odor, it is taken by children quite readily. No disagreeable effects were ever observed. Dr. Maminoff warmly recommends a fair and extensive trial to this very simple, cheap, and easily accessible antimalarial remedy.—*Provincial Medical Journal*, February 1, 1890.

The Treatment of Chronic Gastric Catarrh.—Dr. Robert Saundby insists that patients suffering from chronic catarrh of the stomach should be restricted to three meals a day, at fixed hours, the most suitable being: breakfast, eight to nine; luncheon, one to two; dinner, seven to eight. No food between these meals should be allowed. On rising in the morning the patient should sip five or six ounces of quite hot water, with or without a teaspoonful of Carlsbad salt dissolved in it, according to the state of his bowels. The salt may be taken every other morning, but the water every morning. This will wash the stomach clear of the decomposing mucus. If there is much nausea, it is very good practice to give an emetic the first morning—half a drachm of zinc sulphate with plenty of water.

Breakfast.—If the stomach is very irritable, no hot drinks, such as tea, coffee, or cocoa, should be allowed, but a cup of cold milk and water substituted. Afterward cocoa or chocolate may be taken, with very little sugar. Boiled fish, boiled or poached eggs, or a little smoked or salted ham, may be eaten with two small slices of dry toast, but fats should be taken very sparingly. No fruits, vegetables, or sweets should be allowed.

Luncheon.—Two arrowroot biscuits, or small slices of toast; oysters (with lemon juice, not vinegar); a mutton chop; a slice of cold meat, fowl, or game: milk pudding, aërated water.

Dinner.—No soup. Boiled white fish; stewed sweetbreads, tripe; lightly cooked beef or mutton, roast or boiled; fowl or game; no pork or veal; no vegetables except a little well-cooked potato: milk or custard pudding, jelly; no fruit or pastry; no cheese. No beer or spirits. Aërated water is the best drink. A glass of claret, with aërated water, is permissible—no other wine.

In this list it is to be especially noted that all fruits and vegetables (except a little well-cooked potato) are excluded: this is of great importance; a grape-skin or a piece of indigestible carrot will stir up an amount of irritation in a catarrhal stomach that will require many days to allay. On the other hand, animal food, if not overcooked, is easily digested, and offers no mechanical resistance to the coats of the stomach. Vinegar, sugar, and beer are to be avoided, because they increase the acetous fermentation. Fats are liable to retard digestion, as are tea, coffee, spirits, and all wines, except champagne; but a little claret with aërated water, or a glass of champagne, may be taken if desired. Pastry, cheese, veal, pork, lobster, crab, hot and spiced dishes, ices, and iced water are all known to be either indigestible or irritating, so should be expressly excluded.

If there is any pain or irritability, bismuth and rhubarb may be taken before meals. Where, however, the symptoms point more to sluggish digestion, fulness, and weight after meals, ten drops of dilute hydrochloric acid may be given in a wineglassful of water an hour after each meal, or the following mixture:

R.—Dilute hydrochloric acid	2 drachms.
Dilute hydrocyanic acid	1 drachm.
Strychnine	½ grain.
Glycerin	½ ounce.
Water	5 ounces.—Mix.

Of this a tablespoonful should be taken in water one hour after each meal.—*Provincial Medical Journal*, February 1, 1890.

Iodinated Muslin.—Taking advantage of the property possessed by cellulose of fixing iodine, which is afterward set free under the influence of gentle heat, "iodinated squares," to be used in the same way as ordinary mustard leaves, are proposed. It is said that the iodinated muslin has certain advantages over applications of the tincture of iodine, causing less irritation, so that the effects of the iodine can be longer continued. The fabric is prepared by first placing for a few minutes in a two per cent. sodium bicarbonate solution. It is then washed and pressed and immersed for half an hour in a four per cent. solution of calcium chloride. Following this it is washed until the reaction is no longer alkaline, and placed in a five per cent. solution of hydrochloric acid for fifteen minutes, after which the acid is washed out and the muslin dried. Finely pulverized iodine is now spread upon both sides, the fabric is loosely rolled and placed in a glass-jar. This is heated until vapors of iodine begin to arise, when it is sealed and placed for two hours in a water-bath at 212° F. On cooling, the muslin is ready for use.—*American Journal of Pharmacy*, February, 1890.

Formulæ for Dyspepsia.—HUCHARD points out certain means of combating dyspepsia and the prevention of flatulency. Among the medicaments he considers chloroform one of the best, but on account of its local irritating action it must not be employed in its pure condition or in capsules, as so often ordered. The best form is saturated chloroform water, after one of the following formulæ:

R.—Saturated chloroform water	4 ounces.
Distilled water	3½ "
Mint water	1 ounce.—M.

One teaspoonful to be taken with each meal.

R.—Sat'd chloroform water, Orange-flower water	of each 4 ounces.
Tincture of anise	2½ drachms.

To be given as above.

In the following preparation the chloroform is associated with the excitants of the muscular walls of the stomach:

R.—Tincture of gentian, " " anise, " " nux vomica	of each 1 drachm.
Chloroform	20 to 40 drops.

Mix and filter. Take from ten to twenty drops in a little water fifteen minutes before eating.

When the so-called absorbent powders are preferred, the following may be prescribed:

R.—Powdered poplar charcoal	2 drachms.
Sodium bicarbonate	1½ "
Calcined magnesia	1 drachm.
Powdered calumbo	½ "

Mix, and divide into forty powders. Take one powder an hour or half an hour before meals.

If, at the same time, an antiseptic action is desired, the following may be given:

R.—Beta-naphthol, Salicylate of bismuth, Magnesia	of each 75 grains.

Mix, and make thirty powders. To be administered as the preceding.

The following is useful as an aid to digestion:

R.—Pancreatin, Sod. bicarb. or benzoate, Magnesia	of each 1 drachm.
Powdered nux vomica	5 grains.

Divide into twenty powders, one of which is to be taken before each meal.—*Journal de Médecine et de Chirurgie*, January, 1890.

SATURDAY, MARCH 1, 1890.

THE INFLUENCE OF MENSTRUATION UPON LACTATION.

From the earliest periods of medical history, the idea that the return of menstruation has an injurious influence upon the milk of a nursing woman has found many supporters. At the present day this opinion is generally entertained by the laity and by a large number of practising physicians, although it had its origin in absurd hypotheses in regard to milk formation and the nature of the menstrual discharge. Recent investigators, it is true, have stated that the quantity and quality of a woman's milk are altered by the reappearance of the menses, and one observer claims that human milk, during menstruation, contains bacteria. The first assertion rests upon a study of meagre material; the last is incorrect. The best work yet done in this important field has recently been published in the *Wiener klinische Wochenschrift* (Nos. 51 and 52, 1889, No. 5, 1890, "Ueber den Einfluss der Menstruation auf die Lactation," F. Schlichter). In the Foundling Asylum for Lower Austria, during a period of five and a half months, careful watch was kept over the general health, evacuations, and weight of fifty-two children, suckled by women in whom menstruation had appeared, and thirty-three milk analyses were made. The work appears to have been done most carefully, and the conclusions arrived at, which we quote, deserve attention. "The increase of weight in children suckled by menstruating women is, in many cases, extraordinary."

"The average increase in weight is greater during and directly after the appearance of menstruation than before."

"The condition of the child during menstruation in its nurse is all that could be desired."

"During the so much dreaded menstruation, but a single child became dyspeptic; the dyspepsia, however, did not interfere with a normal gain in weight in this child."

"The milk analyses showed, on the average, less difference between the milk of a non-menstruating and a menstruating woman, than between the specimens of milk taken from one individual at morning, noon, and evening." The paper closes with the four following conclusions, which we have modified by the insertion of qualifying phrases, in parentheses.

1. Menstruation returning during lactation—that is, after the sixth week from delivery—is not (necessarily) injurious to mother or child.

2. Metrorrhagia before the sixth week may retard the development of the child. (This is true during later periods of lactation as well.)

3. Diseases in the nursing child, as dyspepsia, colic, enteric catarrh, occurring during menstruation in the nurse, should be regarded as coincidences and, therefore,

4. Should not, *a priori*, be treated by a change of nurses (or artificial alimentation), but should be managed in the usual way (by medication and regulation of the length of the nursings and of the intervals between them).

These statements are in accord with our own opinion, based on clinical observation, that menstruation, not excessive in amount or duration, nor accompanied by other pathological conditions, does not, of itself, interfere with lactation.

MORE MEDICAL IGNORANCE.

In The Medical News for November 16, 1889, we called attention to the answers which had been given by some of the candidates before the Medical Examining Board of Virginia, and now our attention is called to an editorial article in the *Northwestern Lancet*, giving some of the answers to the questions of the medical examiners of Minnesota. In one instance the candidate stated that "The symptoms of œdema of the glottis are that the patient

feels husky and has sore throat. I would amputate, if necessary; I would do the operation within three or four months, if it was a bad case." "The dose of the sulphate of morphia for a child of five years, hypodermically, would be one-quarter of a grain, and if that did not give relief I would give half a grain." To the question, "What is an element?" the answer was given, "Earth, water, wind, and fire." Trismus neonatornm was defined as "A peculiar trouble of the eye, generally congenital, with falling of the lids, which give an unnatural look to the ordinary face of a child." Another candidate stated that "The sympathetic system is composed of all the filaments of nerves that start from the spinal cord and are destributed to all parts of the system, especially the brain. The cervical portion ramifies the encephalon in general. The dorsal portion ramifies the anus." Another enterprising individual, when asked for the distinctive histological features of carcinoma, replied that "Carcinoma will show a general dropsical condition, transparent condition of all the fluids except the urine, which may show considerable deposit, scanty and hot. The patient's puls is heavy, large, does not care to move."

In the editorial to which we have already alluded, we attempted to show that the lack of interest on the part of the laity and some members of the profession is constantly endangering the lives of a very large portion of the inhabitants of this country.

Is it not possible for physicians once more to make an effort to obtain some such law in Pennsylvania as they have in Minnesota? And is it not a crying evil that one of the younger States of the Union should be so far in advance of one of the oldest?

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

THE PRESIDENT, GEORGE W. JACOBY, M.D., IN THE CHAIR.

DR. IRA VAN GIESON read a paper entitled,

A CONTRIBUTION TO THE PATHOLOGY OF THE LARYNGEAL AND OTHER CRISES IN TABES,

and described a case of tabes with laryngeal attacks during the last year of illness. One of the crises proved fatal. Microscopical examination showed the lesions of a chronic neuritis of the roots of the vagus and accessory portion of the spinal accessory nerves on both sides. Neuritis of the root fascicles or trunks of one or both of these was regarded as more frequently the cause of the laryngeal crises than central lesions.

The author divided laryngeal crises into two classes: First, those in which the glottis constrictors and dilators were normal and the crises occurred from reflex spasm of the adductors. Second, a larger class of cases in which the constrictors and dilators were in a greater or less degree of paralysis.

The first form of the crises might be produced by a neuritis of the roots of the accessory portion of the eleventh nerve, irritating the sensory fibres of the larynx, and being responded to by motor impulses through the vagus, which would produce closure of the glottis by contraction of the adductors. The second form of the crises might be produced by a destructive stage of the neuritis in the vagus, inducing a motor inability of both the adductors and abductors. But as it has been shown experimentally in animals that the adductors are stronger than the abductors, a reduction of power in both sets of muscles would render the equilibrium of the two sets of muscles so unstable that reflex irritation of the motor laryngeal fibres, or direct irritation of these fibres in the vagus by the neuritis would be responded to by a contraction of the stronger adductors, analogously to the results of artificial stimulation of the motor larnygeal fibres in animals. When the neuritis affects both the vagus and accessory nerves together the conditions are favorable for the production of violent crises. A localization of the lesions causing the other crises in tabes was based on Gaskell's description of the distribution of the sympathetic system.

DR. A. SCHAPRINGER presented a case of

CONGENITAL BILATERAL ABDUCENS PARALYSIS WITH FACIAL PARALYSIS.

The patient was a girl, eight years old, with congenital paralysis of both facial nerves and inability to rotate the eyeballs either to the right or to the left. Rotation of the eyeballs upward and downward was unimpaired, as was convergence. This condition of the motor apparatus of the eyeballs is termed by certain authors "bilateral abducens paralysis," which designation Dr. Schapringer considered insufficient and misleading, and he therefore proposed the term "bilateral pleuroplegia" as a substitute. There were only four similar cases on record, viz., one each described by Alfred von Graefe, G. C. Harlan, Julian Chisolm, and P. J. Moebius. Other coexistent anomalies present in the child were: a protuberant glabella, bilateral epicanthus, a slight deformity of the terminal phalanx of the left index-finger, a bifid uvula, and a sunken sternum representing a rudimentary form of "funnel chest." There was also a partial implication of the motor portion of the fifth and of the hypoglossal nerves.

Dr. Schapringer considered the phenomena within the sphere of the cranial nerves as due to a lack of development of the brain involving the nuclei of the fifth, sixth, seventh, and twelfth nerves.

DR. C. A. HERTER then read the history and report of the autopsy of a

CASE OF CERVICAL PARAPLEGIA FROM DISLOCATION.

J. F., a mason, fifty-seven years of age, fell head first from a scaffolding, a distance of twelve feet, striking with his head against a board. The patient was conscious on admission to the hospital. Examination failed to elicit evidence of fracture or dislocation in any part of the

cervical spine, but there was great tenderness of the sixth and seventh vertebræ. There was complete motor paralysis below the arms. The forearms and arms were normal, but there was weakness of the muscles of the hand. There were also anæsthesia and analgesia of the lower extremities, and of the trunk extending high on the chest. On the arms the anæsthesia involved, roughly speaking, the distribution of the ulnar, internal cutaneous, and lesser internal cutaneous nerves, and was symmetrical.

With the exception of the plantar reflex of the left side, both superficial and deep reflexes were absent when the patient was admitted. There was a cincture pain about the lower part of the neck, and above and below the clavicles there was hyperalgesia. Below the neck there was pronounced myoidema, and fibrillary contraction could readily be elicited. Respiration was purely diaphragmatic; temperature on admission 97.2°. Retention of urine and incontinence of fæces.

Nine hours after admission the sensory loss was unchanged, but the motor paralysis had spread, so as to involve the flexors and extensors of the wrist, the triceps, and to a less extent the pectoralis major, and the pronators and supinators. Very slight power remained in the biceps. Respiration continued diaphragmatic. The pulse was somewhat feebler than on admission, but good. The temperature had risen during the afternoon following admission to 104°.

On the day following admission the patient's condition was about the same, except that the biceps was somewhat feebler. During the afternoon of this day there was some embarrassment of respiration, and on the second day after admission the patient died from respiratory failure, having survived the injury forty hours.

The autopsy revealed a dislocation forward of the sixth cervical vertebra, and an oblique fracture through the left superior articular process of the sixth vertebra. The forward displacement of the sixth vertebra was probably not more than one-third of an inch. How much pressure was being exerted on the cord at the time of the autopsy could not be determined. Examination of the cord showed that the eighth cervical segment was extensively disintegrated, and that the seventh was considerably softened by the displacement of the vertebra. At the junction of the sixth and seventh segments the central canal was distended by hæmorrhage, and there seemed to be some extravasation into the surrounding gray matter. Above the sixth segment the cord was normal. The case supported the view that the peculiar distribution of the sensory disturbance noted in the upper extremities depended on a lesion of the eighth cervical and first dorsal segments, and that in this case the biceps was represented at a lower level than is considered usual—*i. e.*, in the lower part of the sixth segment.

CORRESPONDENCE.

PARIS.

Typhoid Fever in Paris.

To the Editor of The Medical News.

Sir: Before entering upon this subject, it is necessary, I think, to explain in as few words as possible, the distribution of drinking water in the city of Paris.

In this city, water is derived from several sources: spring water and river water (Seine water). The spring water is very scarce, and is only distributed to a certain number of the twenty districts into which Paris is administratively divided. This spring water is obtained through canals as near to the source as possible, so as to prevent its pollution by passing through crowded cities. The quantity, however, is very small, as compared to the amount used by the whole city; hence, the water of the Seine, which passes through Paris, after having passed through several large cities, is used. This has become infected by the sewage of the other cities before it reaches here, and is supplied to the majority of the districts. I must say, however, that the city is now engaged in extensive works to secure a spring water supply, so as to be able to avoid altogether the consumption of river water by the inhabitants, which is now plainly proven to be the cause of the large amount of typhoid fever in Paris.

The authorities, as a matter of justice to all the inhabitants, have conceived the idea of giving spring water for a certain length of time to many districts of Paris, while during the remainder of the year these same portions of the city are supplied with river water; each district taking its turn. The result of such a distribution is the dissemination of typhoid fever throughout all the districts instead of keeping it localized to a certain number.

About three years ago, two prominent and well-known physicians of Paris, Professor Chantemesse and Dr. F. Vidal, stated that the Seine was the principal cause of the typhoid fever epidemic observed in this city; founding this opinion on the fact that whenever *river* water was distributed to a certain number of districts, three weeks later the number of typhoid fever patients admitted into the hospitals from these quarters was three or four times greater. Some physicians at the time objected to this opinion, and believed that the real cause of the disease was not the distribution of water, but the influence of the season; as in summer, the number of cases of typhoid fever is always high. They claimed that the contamination by water was a mere coincidence. To this the above-named gentlemen rightly objected, that during the winter of 1887, an accident having occurred to the canal which brings the spring water to Paris, the river water replaced it for several weeks, and during that time the mortality from typhoid fever ran up to as high a percentage as in the middle of the summer.

Another objection was, that if the Seine water was the real cause of the disease, the disease would only present itself in quarters where this water is distributed, while cases of typhoid fever are observed in districts receiving spring water. But the objectors forgot the fact that most of the persons who are liable to be attacked by typhoid fever, young men, are, during the day, in different parts of the city, where river water is used.

The year 1888, having been a very rainy one, and consequently the amount of water used for sprinkling the streets having been greatly decreased, river water was not substituted for spring water in most of the districts, and the statistical results show that at the end of the year the percentage of deaths from typhoid fever had decreased to a smaller number than for thirty years. Observing the statistics we find, that while spring water was

being distributed to the city, the number of cases of typhoid fever admitted in the hospital was as follows:

April 7, 1889, to April	13th,	. .	22 cases.
" 21, " " "	27th,	. .	15 "
" 28, " " May	4th,	. .	26 "
May 5, " " "	11th,	. .	47 "
" 12, " " "	18th,	. .	33 "

On May 25th, the city authorities began to substitute river water for the spring water, and we find the following number of entrances:

May 26th to June	1st,	. . .	18 cases.
June 2d " "	8th,	. . .	26 "
" 16th " "	22d,	. . .	39 "
" 23d " "	29th,	. . .	48 "
July 7th " July	13th,	. . .	73 "
" 21st " "	27th,	. . .	127 "
Aug. 4th " Aug.	10th,	. . .	120 "
" 11th " "	17th,	. . .	129 "

As was previously indicated by MM. Chantemesse and Vidal, it will be observed that three to four weeks after the substitution of Seine water for the spring, the cases of typhoid began to increase, and became more and more numerous as more river water was given. The number of deaths is much greater in those districts which use river water.

It remains now a fact well proven, and admitted by all physicians in Paris, that the mortality from typhoid fever is three to four times higher in districts supplied with river instead of spring water.

Dr. Schneider, of the French army, has made similar observations to the preceding, in the Department of War. While spring water was distributed to the troops only ten cases of typhoid fever were observed in the whole Paris garrison during the month of October. On October 31st, for some reason, river water was substituted, and from November 8th to November 21st, 14 cases entered the military hospitals; from November 22d to November 30th, 34 cases; and from December 1st to December 12th, 41 cases were admitted. As an additional proof, five barracks, including about five hundred soldiers, were kept on spring water, and during the period from November 22d to December 12th, which was particularly unfavorable, as shown above, not one single case of typhoid fever was observed in those barracks. Hereafter the Secretary of War has decided, that nothing but spring water shall be distributed to the soldiers.

The bacteriological researches made by Professor Chantemesse and Dr. Vidal, in the early part of 1887, led them to the conclusion that the only safeguard against typhoid fever, for those who were compelled to drink river water, was to have the water boiled for at least ten minutes.

MILWAUKEE.

To the Editor of The Medical News,

Sir: The city of Milwaukee can hardly be considered a medical centre. It has not its struggling, poorly supported and half-equipped medical college or university which is the boast and burden of the local profession of many cities of lesser size and importance. It is doubtful if there is another American city of the size of Milwaukee without its one or more medical colleges. In these days of multiplying institutions of medical instruction, this fact is not to be regretted by those who look to the best interests of higher and more thorough medical education.

The city contains a population of two hundred and ten thousand, with about the average proportion of doctors, among whom are representatives of almost every medical college in the United States, and a considerable proportion of graduates of foreign institutions. The climate and location make it one of the healthiest of American cities. Although the population is largely foreign, the intelligence and hospitality of its people render it a most desirable place of residence.

With hospitals Milwaukee is fairly well supplied. The Milwaukee County Hospital is located at Wauwatosa, a suburb just west of the city. The removal of this hospital to the city is a subject discussed among the physicians and the county officials, but the question is still undecided. By the majority of the physicians of the city it is thought that the usefulness of the institution, both to the public and to the profession, would be largely increased by its removal; there are, however, hospitals within the city where cases of injury and disease may be well cared for, and the question at issue is, perhaps, one of economical management rather than one of necessity. Within the city proper, St. Mary's Hospital and Passavant Hospital are the two leading institutions, each with its appointed medical and surgical staff. The hospitals just named both admit charity cases upon proper recommendation, and also afford facilities whereby a patient may be furnished with a bed or private room, and be treated by any physician whether he be a member of the hospital staff or not. With these should be mentioned St. Joseph's Hospital and the Emergency Hospital. The latter has been established about a year and a half, has an efficient medical and surgical staff, is the most centrally located, and the work done since its establishment has fully demonstrated the necessity for such an institution. The Elms Hospital for Women and Trinity Hospital are private institutions.

The Wisconsin Training School for Nurses, attached to the Milwaukee County Hospital and the Elms, also deserves mention in this connection. It is an institution conceived and conducted by a number of benevolent and enterprising ladies of the city, their first annual report appearing in October last. The work already done and the evidence of an extending field of usefulness are in every way creditable and encouraging to the promoters of the institution.

There are several medical societies in which the profession of the city are represented, but none exists in which the physicians of the city are interested as they should be. A good city medical society is at present a *desideratum*. The Society of German Physicians and the Clinical Club are good in their way, but the membership in both is limited. About one-fourth of the physicians of the city are members of the State Society, and a still smaller proportion are members of the Rock River Medical Society, a district society which with its quarterly meetings has the reputation of doing most excellent society work.

We have in our city the best medical library west of Philadelphia, a private collection of twenty thousand volumes; the hospitality of its shelves is kindly extended to the profession of this and neighboring cities by its

generous owner, Dr. Senn. The Clinical Club has in its rooms a good collection of books, numbering about a thousand volumes, the library of the late Dr. John K. Bartlett, with some additions. The Club also places before its members a very complete list of medical periodicals, both American and foreign. To this collection of books and current literature the profession of the city may also have access.

A somewhat amusing case has recently come up in our city court. It appears that some time after an external urethrotomy, a man died suddenly, and the physician who made the autopsy, observing a fistulous opening in the cicatrix, stated incidentally that the subject was an hermaphrodite. This getting into the hands of a reporter, and appearing in one of the city papers in an objectionable way, the widow of the deceased sued and recovered damages in small amount from the newspaper.

Dr. Senn has recently received an invitation tendered by the Committee on Surgery, and by von Bergmann, President, of the Tenth International Medical Congress, to be present at Berlin in August next, and deliver a lecture on intestinal surgery, with demonstrations—a fitting honor to one who, by reason of his skilful and original investigations, stands, in this special department of surgery, *facile princeps*. The invitation has been accepted.

BALTMORE.

To the Editor of The Medical News,

Sir: On December 17th a movement was started in the city of Baltimore, having for its object the improvement of medical education primarily in Maryland, and secondarily all through the United States. In order that a meeting might be held, consisting of the most representative and most interested men on this subject, the following letter was widely distributed among the profession, and signed by the most prominent men in Baltimore and Maryland:

"With a view to joint action on the part of our five medical schools, it is proposed to hold a meeting of representatives from the faculties to discuss the feasibility of introducing reforms. It is thought that a joint action will render the difficulties to be met easier to deal with, and it is hoped that your interest in higher medical education will induce you to bring the matter before your faculty at the earliest practicable moment, with a view to the appointment of a committee of conference. January 15th at 1 P. M., the hall of the Medical and Chirurgical Faculty of Maryland, is named as the time and place of the meeting. Yours respectfully,

"Jackson Piper and others."

In response to this call, a meeting of the representatives of the various colleges in Baltimore was held on January 15th, and was largely attended. As a result of the meeting, the following circular was drawn up and the secretary instructed to send a copy to all the Medical Schools and Boards of the United States:

"*To the Medical Colleges of the United States:* The Baltimore medical colleges and the Johns Hopkins Hospital, having met for the consideration of reforms urgently needed in the system of medical education hitherto in operation in this country, after a full discussion of this most important subject, have come to the conclusion that it is not expedient, nor, indeed, practicable, for the medical schools of any State to assume alone the responsibility of adopting advanced methods; yet, fully convinced of the pressing need of a change, and earnestly desirous to see it consummated, they are unwilling to let matters rest longer as they are, without at least an effort on their part to improve them. They have determined, therefore, to issue this appeal to the medical schools of the United States for their coöperation in inaugurating a national advance. Fully aware of previous ineffectual efforts in this direction, they yet realize that times have greatly changed since those efforts were made, and they believe that a repetition of them at this time would have a good prospect of success. The approaching meeting of the American Medical Association, drawing delegates, as it will, from every part of the country, offers a good opportunity for convening those who are interested in the contemplated change. We therefore invite you to join with us in holding a conference for the full consideration of 'medical education in this country, and measures for its improvement,' and we request that you will appoint at your earliest convenience one or more delegates from your faculty to represent it at a meeting to be held at Nashville, Tenn., on the 21st of May, 1890, at 3 P. M. It is requested that delegates should be instructed as far as possible as regards the wishes of their faculties upon the various measures now proposed in connection with advances in medical instruction, in order that definite results may be arrived at with the least possible delay and trouble. The following subjects are considered as most likely to come up for discussion:

"1. Three years' course of six months' sessions.
"2. Graded curriculum.
"3. Written and oral examinations.
"4. Preliminary examination in English.
"5. Laboratory instructions in chemistry, histology, and pathology."

OLDEST LIVING GRADUATE OF THE UNIVERSITY OF PENNSYLVANIA.

To the Editor of The Medical News,

Sir: An item in a recent number of The Medical News states that Dr. I. L. Coffman, of Phœnixville, Pa., is said to be the oldest living graduate of the Medical Department of the University of Pennsylvania, he having been practising sixty-one years. It may be of interest to note that Dr. T. T. Slaughter, of Madison County, Va., who has practised medicine continuously up to within the last year, graduated from that institution in 1825, and practised his profession for sixty-four years. He is now in the eighty-sixth year of his age.

Yours truly,
R. W. Slaughter.

NEWS ITEMS.

Modern Dissecting Tables.—At the Morgue in New York City new dissecting tables are to replace the antiquated ones now in use. They will be fitted with movable gas-jets, hot and cold water, and spray pipes, and an adjustable joint, so that the bed of the table may be shifted to

any angle desired. A newspaper item quotes one of the medical attachés of the Coroner's office as saying that the cost of a modern table is between $500 and $800, according to the completeness of its outfit.

An Antirabic Institute at New York.—A Pasteurian Institute was inaugurated in New York City, in a very quiet way, on February 16, by Dr. Paul Gibier, recently of Paris, the director of the institute. He will be assisted by Drs. Van Schaick and Lieutard. The present location of the institute is No. 198 West Tenth Street, where it will be conducted by Dr. Gibier at his own expense, and the poor will be treated free of charge, as is done by Pasteur in Paris. Dr. Gibier was, for many years, the first assistant to Pasteur; and it is by the advice of the latter that the undertaking has been located at New York. One patient, a boy, has already been admitted to the institute, and is under treatment by Dr. Gibier.

A Bogus Hospital receives Public Money.—The "Sanitarian Hospital" of Brooklyn is under a cloud. Its proprietor has been indicted by the grand jury for larceny, on account of obtaining charitable funds from the public treasury without furnishing a hospital service. The indicted physician is said to be an eclectic, and extracts from his so-called minutes show that he is without education, few words being correctly spelled.

Medical Examinations in Germany.—The last annual report of the Board of Medical Examiners of Prussia shows that of 683 candidates, 504 were passed; the percentage of successes being 74, failures 26.

Regulation of Medical Practice in the District of Columbia.—A bill has been introduced into the Senate of the United States establishing a Board of Medical Examiners in the District of Columbia. This board will be composed of ten physicians or surgeons, five practitioners of homœopathy, and three dental surgeons. The term of office, according to the bill, will be four years.

The Value of American Diplomas in Berlin.—A cablegram states that much indignation has been aroused in the two hundred American medical graduates in Berlin, because the authorities at the university have determined not to recognize as valid any diplomas issued by medical colleges in the United States.

Surgeon T. H. Parke.—Surgeon Parke is temporarily doing duty at the hospital at Cairo. The following paragraph was written by a correspondent who accompanied the Stanley party on their way to the coast: "Surgeon Parke is a young medical officer of the British army, and a native of Dublin. Like Stairs, he had to obtain leave of absence for the purpose of joining the expedition, and he is also a volunteer serving without pay. On all sides the correspondent heard nothing but the highest praise of Parke. Surgeon Parke met Emin Pasha at the same time as Stanley did, and was present at their first memorable interview." He is but twenty-six years old.

A Possible Source of Lead-poisoning.—According to Mr. Herbert Whitby, of England, a possible source of lead-poisoning in that country exists in the "tons upon tons of lead scattered over the land by sportsmen. In some places on the moors the ground is literally paved with lead, and the effects are terrible to contemplate when it is considered that water from the moors forms part of the water-supply of many towns." Fortunately for us, it must be many years before such a danger can exist in this country.

Death from Snakes and Wild Animals in India.—According to the *Indian Medical Gazette*, the total number of people killed in India by wild animals and snakes, in 1887, was 22,348; in 1888, 22,900. Whether this increase can be accounted for by a proportionate increase in population, and migration to new sections of the country, is not stated.

Obituary.—DR. RICHARD D. LEE, one of the senior members of the medical profession in Harford County, Maryland, died suddenly on February 4th. He was found dead in his carriage, in the public road, near Bellaire. Dr. Lee was graduated in 1848 from the Washington Medical College at Baltimore.

——DR. HEINRICH FREY, of Zurich, died January 23d, of apoplexy supervening upon an attack of epidemic influenza. He was Professor of Anatomy in the University of Zurich, and was well known in the scientific world by his works on the microscope and on histology, which have been translated into the principal European languages. He was in his sixty-ninth year.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 18 TO FEBRUARY 24, 1890.

By direction of the Secretary of War, the retirement from active service, on February 9, 1890, by operation of law, of ANDREW K. SMITH, *Colonel and Surgeon*, under the provisions of the Act of Congress approved June 30, 1882, is announced. Colonel Smith will proceed to his home.—Par. 1, *S. O. 34, A. G. O., Washington, D. C.*, February 9, 1890.

RAYMOND, HENRY J., *Assistant Surgeon.*—Is promoted to be Assistant Surgeon with the rank of Captain, after five years' service, in accordance with the Act of June 23, 1874.

KNEEDLER, WILLIAM L., *Captain and Assistant Surgeon.*—Upon being relieved from duty by Captain Robinson, will report at Jackson Barracks, Louisiana, for duty at that station, relieving Freeman V. Walker, First Lieutenant and Assistant Surgeon. Upon being relieved, Assistant Surgeon Walker will report at Fort D. A. Russell, Wyoming Territory, for duty at that station.—Par. 4, *S. O. 43, A. G. O.*, February 20, 1890.

ROBINSON, SAMUEL Q., *Captain and Assistant Surgeon.*—Now on duty at Fort Hamilton, New York, is relieved from duty in the Division of the Atlantic, and will report in person to the Superintendent U. S. Military Academy, West Point, New York, for temporary duty at the Academy, to relieve William L. Kneedler, Captain and Assistant Surgeon.—Par. 4, *S. O. 43, A. G. O.*, February 20, 1890.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

SOME CASES TREATED WITH IODOL.

BY DAVID CERNA, M D.,

ASSISTANT IN THE LABORATORY OF EXPERIMENTAL THERAPEUTICS IN THE UNIVERSITY OF PENNSYLVANIA.

ALTHOUGH comparatively a new remedy, iodol has already been used somewhat extensively by various practitioners in the treatment of those diseases especially for which iodoform has been employed.

This therapeutic agent was brought into notice, in 1885, by Vulpius, of Heidelberg, and by Dr. G. Mazzoni,[1] of Rome, both of whom employed it as an antiseptic in the treatment of wounds. Following these writers, many surgeons and general practitioners have used iodol for the same and other purposes with the most happy results.

Without going into an examination of the literature of the subject, regarding the physiological and therapeutical action of the drug, I may state in general that iodol has been employed advantageously, by various observers, in the treatment of eye affections, and in such diseases as adenitis, blennorrhagia, vaginal catarrh, tubercular laryngitis, and in others of syphilitic origin. It has been found of great service in the treatment of buboes, chancres, and ulcers in general, and has also been used as an internal remedy in most stages of syphilis and scrofulous affections.

In private practice, I have given a fair trial to this new drug, and obtained, in many instances, most excellent results. Among the cases the following are the most important:

CASE I.—R. H., male, of lymphatic temperament, aged fifty-five years, grocer by occupation, had a phagedenic ulcer in lower third of left leg. He had been suffering for about a year, and during that time was treated by several quacks but without avail; he constantly grew worse. When I first saw the patient he was in a bad condition, and suffered greatly both mentally and physically. The ulcer was five centimetres in length, three in width, and one in depth; of irregular form, and, as I have said, phagedenic in character, covered with vegetations which secreted a muco-purulent discharge: edges ragged, indurated, and pigmented; no local, or very slight, venous congestion. Close examination of the patient revealed no syphilitic history. A ten days' local treatment with a solution of corrosive sublimate (1 : 1000), iodoform, a cotton pad and bandaging, did the patient no good. Discontinuing this treatment, I immediately began the use of iodol. The ulcer was cleansed with the bichloride solution, then dusted over with the powdered iodol, using, as previously, the absorbent cotton pad and light bandaging from the foot to a little below the knee. Next day I was surprised to notice a great improvement. The bad odor had disappeared, the edges of the ulcer were much softer, the discharge was lessened in amount, and several cicatricial points had begun to appear. The patient remarked to me that soon after the application of the drug he felt a pleasant itching or tingling sensation which lasted several hours. The same treatment was continued, and a steady improvement observed, until the twenty-eighth day, when the patient was discharged cured.

CASE II.—Mrs. A. C., aged fifty years, housewife, of sanguine temperament. Had been troubled for several months (could not tell the exact time) with ulcerations of both legs; otherwise she appeared to enjoy comparatively good health. It appears that several years ago she suffered from a scrofulous affection as revealed by certain cicatrices on both sides of her neck. Her history, and especially her family's, showed that there was some syphilitic taint in her constitution. On the middle third of the right leg there was an ulcer which was almost round, its mean diameter being three centimetres, its depth one centimetre; edges ragged, hard, somewhat reddened, and on the surface were ugly vegetations discharging an abundant, white, viscid liquid, which had a very disagreeable odor; lesion very tender and bled to the simple touch. There was another ulcer on the left leg, situated on the lower third, and was three centimetres in length, two in width, and about one in depth; in every other respect this presented almost the same characters as the other; but here was noticed a varicose condition of the veins, and the pain and bleeding of the ulcer produced by simple touch were very pronounced. The patient was placed upon ten-grain doses of iodide of potassium daily, and a simple nourishing diet. The ulcers, after being washed with a solution of bichloride of mercury (same strength as last, which is the solution I have generally used in such cases), were touched with nitrate of silver, covered with a cotton pad, over which was placed the usual bandage. This treatment was continued for a week with no apparent good results, either on the general health of the patient nor on the local trouble. The internal administration of medicine was stopped. Iodol was resorted to, and with a view of making a comparative study, iodoform was also employed. The ulcer on the right leg was treated with the former, that on the left leg with the latter drug. The usual dressing was applied to both ulcers. On the next day I found that the lesion of the right

[1] Berliner klinische Wochenschrift, 1885.

limb, the one on which iodol was used, presented the most encouraging results; the bad odor had disappeared, its surface was perfectly clean and free from the crust which iodoform is so apt to form; the indurated borders were much softened, and there was a marked diminution in the viscid muco-purulent discharge. In the ulcer treated with iodoform no improvement was noticed, and it had almost the same appearance as on the previous day. This patient spoke to me also of the agreeable tingling sensation felt in the right ulcer, soon after the application of iodol, and which lasted for several hours. This course of treatment was pursued without interruption, and at the end of three weeks the disease of the right side had entirely disappeared, leaving a good cicatrix. The one treated with iodoform had scarcely improved at all, so that this drug was discontinued and iodol used, and eventually the happiest results were observed. In two weeks longer the patient was completely cured and advised to wear rubber stockings.

Case III.—E. N. G., aged thirty years, of nervous temperament, tailor by trade, applied to me for treatment with two ulcers in the lower third of the left leg, fibular surface, and one on the right leg, also fibular surface, situated on upper third. History revealed a syphilitic taint, the disease having been contracted about eight years before. When he applied to me he was suffering from terrible dyspeptic symptoms, which had greatly weakened his constitution. A few months previously, while under medical treatment, he expelled several yards of tapeworm. His health, however, was but little improved. The ulcers of left leg were about the same size, and measured three and a half centimetres in length, two in width, and one in depth; hard, reddened contours; ragged irregular edges; granulations ugly and oozing pus of a very disagreeable odor. The one on the right leg, five centimetres in length, three in width, and about one in depth, bore almost the same characters as the other two. These were subjected to iodol treatment, while on the other one iodoform was employed. Patient was placed on iodide of potassium, ten grains daily, but the salt was discontinued at the end of six days, owing to aggravated symptoms of dyspepsia, intense frontal headache, and marked coryza—all unmistakable signs of iodism. The ulcers treated with iodol soon showed marks of improvement, and in three weeks were entirely cicatrized; the one under iodoform presented no changes in the same period of time, and was subsequently subjected to iodol with good results.

Case IV.—F. G. S., male, aged forty-five years, of lymphatic temperament, carpenter by trade, was suffering from a tubercular syphilide, involving left ear and end of nose; had contracted the disease about ten years before, and while laboring from secondary symptoms, his wife had two abortions, and a child had died within a year of its birth, undoubtedly from syphilitic disease. The patient was placed upon iodide of potassium, eight grains daily, but in a short time gastric disturbance, frontal headache, and other untoward symptoms of iodism were developed, and the drug was suspended. After several days the medicine was tried again, but only to produce the same disagreeable effects. It was finally discontinued and iodol resorted to. This drug was employed in doses of three grains three times a day, and the writer was pleased to see rapid improvement of the patient, who within six weeks was entirely relieved and cured, for the time being at least, of his local trouble. No constitutional effects were produced by this medicine with the exception of slight diarrhœa, which completely disappeared soon after the discontinuance of the drug. No local treatment was employed.

Case V.—The next case was that of N. G., aged thirty-eight years, a laboring man, of sanguine temperament, who came under my observation with a well-defined phagedenic ulcer of the fauces, involving, to a certain extent, the soft palate and uvula. Cross-examination of the patient revealed a syphilitic history of twelve years' standing. He now suffered from difficulty of swallowing, regurgitation through the nostrils, and snuffling. As regards his general condition, he was a perfect wreck. I immediately placed him upon a strict dietetic regimen, and began the local application of iodol by means of a spray of an ethereal solution. Being a case of a distinct tertiary form of syphilis, and one of the most aggravated types at that, iodide of potassium and protiodide of mercury, twenty grains of the first and half a grain of the second drug were prescribed alternately every other day. The appearances of the local lesion improved rapidly, but, at the end of two weeks, the worst forms of iodism and ptyalism ensued, and, of course, the drugs were suspended. I now resumed the administration of the potassium salt alone, in the dose of twelve grains daily, and a few days afterward the untoward efforts of this therapeutic agent presented themselves, which caused me to abandon it and substitute iodol, also internally, beginning with small doses and gradually increasing the amount to as high as twenty grains a day. At the end of three months from the commencement of the treatment the ulcer was entirely healed, swallowing and the voice returned to normal, and the patient, who, in his own words, "never felt better in his life," was discharged.

The use of iodoform in diabetes mellitus by Moleschott,[1] referred to by Professor James Tyson, of the University of Pennsylvania, in his excellent article on this disease,[2] suggested to me the idea of employing iodol in that affection, as a trial, and I have to report one case in which good results were obtained.

Case VI.—A. E., aged thirty-eight, of nervous temperament, farmer, came under my professional care with the following symptoms: Frequent micturition, especially at night, loss of appetite, great thirst, a disagreeable dryness of the mouth and fauces, and general emaciation. The quantity of urine was certainly greater than normal; he passed, the second day after I first saw him, a little more

[1] Wiener medicinische Wochenschrift, Nos. 17, 18, 19, 1882.

[2] A System of Practical Medicine by American Authors, edited by Professor William Pepper, vol. ii. p. 228.

than three quarts. Microscopical and chemical examination of the urine showed a few epithelial cells, and a very large amount of sugar with Fehling's test. The urine was acid in reaction, with a specific gravity of 1022. Lack of time and of proper apparatus on the occasion prevented me from making an accurate quantitative analysis. The patient was placed on an exclusive milk diet and six grains of iodol daily. Examinations of the urine were made every second day, and it was found that *pari passu* with the decrease in the amount of the fluid there was a marked reduction of the sugar. In one month the sugar was greatly diminished, and the general health of the patient improved in every respect. At the end of two months the diabetic condition of the urine had entirely disappeared, and the patient was discharged as cured.[1]

These are some of the most important cases that have come under my observation, and in which, as may have been noticed, I have had the most excellent results from the use of iodol. These results are certainly very encouraging, and further trials should be given the drug as a local and systemic remedy. Rich as it is in iodine, there is no doubt that its properties are due to this element, as is the case with iodoform; but over iodoform it has advantages, one of the chief being its lack of the disagreeable odor so characteristic of the latter drug. This advantage will be, and is, most noticeable in the treatment of local affections, such as chancres, vaginal catarrh, adenitis, buboes, blennorrhagia, ulcers, and other diseases, particularly in private practice.

Sufficient evidence, I think, has already been brought forward as to the great value of iodol as an internal remedy chiefly in cases that require alterative treatment.

I suggest the internal employment of this new and powerful drug, especially in those syphilitic cases, even of the worst type, which, owing to idiosyncrasies or what not, will not bear long the constitutional effects of mercury and iodide of potassium.

In conclusion, I may state that with regard to the local application of iodol, I have employed it either in powder, solution, or as an ointment. Solutions can be made in alcohol (one part to three), or ether (one to four). I have generally used it as an ointment, one part to four or five of vaseline. Internally, I have given, as it may have been observed, as much as twenty grains a day; but, on high authority,[2] larger doses (thirty to forty-five grains daily) may be employed without producing untoward constitutional effects.

[1] I saw this patient a little over a year afterward. He had gained several pounds in flesh, and appeared to enjoy the best of health. He was then the father of two healthy children (twins).

NOTE ON THE USE OF TURPENTINE IN TYPHOID FEVER.

By H. C. WOOD, M.D., LL.D.,
PROFESSOR OF THERAPEUTICS IN THE UNIVERSITY OF PENNSYLVANIA.

The most useful articles in a medical journal are not those which are the most original, and certainly if lack of originality be a spice of value, the present note in regard to the oil of turpentine in typhoid fever will be well flavored. The employment of the remedy I believe originated with Dr. George B. Wood, and was certainly very strongly inculcated by him, so that it has been amusing and instructive when from time to time, especially in some of the English journals, it has been brought forward as a new discovery by medical writers. Dr. George B. Wood taught that the oil of turpentine acts as a local remedy in typhoid fever, and that there are two stages of the disease in which it is especially useful. The first is at the end of the second week, when the tongue becomes especially dry and glazed, and the abdomen very distinctly tympanitic, with or without the coexistence of diarrhœa. The second period in which the remedy was especially used by the former Professor of Therapeutics in the University was during convalescence, when the perpetually recurring diarrhœa, with lack of digestive power, indicated failure of some of the intestinal ulcers to heal. For nearly twenty-five years I have been following the practice of my predecessor, and I am very thoroughly convinced by experience in hospital and in private practice that many lives would be saved if the oil of turpentine was more freely used in this disease. I do not believe that it is possible to reach the ulcerations in the small intestine with nitrate of silver, or other similar readily decomposable or readily absorbable remedy. The volatile oils are absorbed slowly, and are rapidly vaporized at the temperature of the human abdomen, so that there can be no reasonable doubt that, either in the form of liquid, or more probably in the form of vapor, when given freely by the mouth, that they get into contact with the mucous membrane of the upper intestine. It has become my routine habit to give the turpentine in every case of typhoid fever, beginning about the twelfth or fifteenth day, and I believe if its use were habitual in the profession there would be much fewer cases of intestinal hæmorrhage or other severe symptoms due to a local lesion.

In my own case convalescence from typhoid fever was exceedingly slow on account of the perpetually recurring diarrhœa, and when at the instance of Dr. George B. Wood himself, then an old man nearly eighty years of age, the turpentine was exhibited, the local symptoms were relieved immediately. Four or five times I experimented by stopping the turpentine, and when local symptoms had returned, on giving the turpentine again, would see them abate within

twenty-four hours. The effect of the drug was scarcely mistakable. The turpentine may be disguised by means of glycerin and a volatile oil made into an emulsion, which is rarely objected to by patients. Ten or fifteen drops should be given every two hours during the day, the patient being allowed to rest at night. The following formula will be found satisfactory:

R.—Ol. caryophylla . . . . gtt. vj.
Ol. terebinth. . . . . fʒjss.
Glycerin, } . . . āā fʒss.
Mucil. acaciæ, }

Aquæ, }

Sig.—Dessertspoonful as directed.

A STUDY OF VILLOUS TUMORS OF THE BLADDER.[1]

By CHARLES N. DIXON JONES, M.D., B.S.,
of Brooklyn, New York.

Whenever a case of severe and often-repeated hæmaturia comes under observation, the physician has a specimen of the bloody urine submitted to an examination with the microscope, in order to establish a correct diagnosis in regard to the site and cause of the hæmorrhage. Such a diagnosis cannot, however, always be obtained, even though the examination be undertaken by the most skilful microscopist, and especially is this so if the amount of blood present in the urine be excessive. An experienced microscopist may spend many hours of faithful examination without being able to determine the seat of the hæmorrhage.

Every hæmorrhage in the genito-urinary tract must, of necessity, cause a detachment of a certain number of shreds of connective tissue. Between the walls of the bloodvessels and the outer covering there is a layer of connective tissue which must, as a matter of course, be torn off by the current of blood at the spot where the rupture of the vessel occurs. The amount of connective tissue, however, may be so small that it escapes altogether the attention of the microscopist. This occurs more especially when the rupture takes place in the venous bloodvessels of the mucosa of the bladder, as in these instances the veins are in a state of varicose enlargement, a condition which was termed by the older pathologists "hæmorrhoids of the bladder."

I know, for instance, of a case in which urine heavily loaded with blood was sent to a microscopist for examination. He was unable to locate the site of the hæmorrhage, whereas, the surgeon (the late Dr. Carnochan) positively asserted that he could start the hæmorrhage by introducing a sound into the neck of the bladder. Probably this was an instance of dilated veins at the neck of the bladder, rupturing spontaneously or upon the slightest touch with an instrument.

When, however, the shreds of connective tissue are numerous, being found mixed with the sediment at the bottom of the vessel after the voided urine has stood at rest for a period of six or eight hours, a diagnosis as to the source of the hæmorrhage is, in most instances, possible. Such shreds are voided with bloody urine in either of four instances:

1. In ulceration of the mucosa of the genito-urinary tract—mainly the bladder, but sometimes the urethra or the pelves of the kidneys.

2. In a suppurative process after the rupture of an abscess, and in which shreds of the so-called membrana pyogena are readily detached.

3. In cases of tumors, most frequently of the bladder.

4. A rather common cause is the presence in either the bladder or the pelvis of the kidney of a foreign body in the form of a calculus.

The calculi in the pelves are invariably made up of uric acid or oxalate of lime; in the bladder, on the contrary, they may be composed of alkaline phosphatic salts, deposited primarily or around a nucleus, passed from the pelvis through the ureters.

Traumatism may, as a matter of course, be instrumental in rupturing bloodvessels and causing the appearance of sloughs and shreds of connective tissue in the urine. In order to establish a positive diagnosis as to the source of the hæmorrhage, the epithelium, so markedly different in different portions of the genito-urinary tract, will prove of inestimable value to the microscopist. For no one will doubt that in every instance of a rupture of bloodvessels on the mucous surface a certain number of the epithelial cells covering the particular spot of injury will be detached. Such epithelia will be of diagnostic value in cases of traumatism, ulceration, and abscess. But if the hæmorrhage be due to the presence of a tumor, the epithelia detached will prove of comparatively little service, since we know that the tumors themselves are covered with either cuboidal or columnar epithelium, which varies greatly both in size and shape, and will not enable us to determine the location of the tumor. Quite recently I examined the urine of a woman thirty-eight years of age, which was loaded with blood. The patient was subject to repeated attacks of hæmaturia with intervals extending to days or even weeks, in which the urine was free from blood. Under the microscope I found, in addition to pus and red blood-corpuscles, numerous epithelia of the kidneys, a few epithelia from the pelves of the kidneys, and a few resembling those of the middle layers of the bladder. My conclusion was that the organ exhibiting its epithelia most lavishly must be the site of the hæmorrhage. Therefore, my diagnosis was:

[1] Read before the Brooklyn Medical Microscopical Society, January 8, 1890.

"Hæmorrhage from the kidneys due to pyelo-nephritis," the more positive, as I encountered a certain number of granular casts.

The clinical examination of this case disproved my diagnosis. I found in the mucosa of the urethra a papillomatous growth, freely supplied with blood-vessels, the so-called caruncle, which bled furiously upon being touched with the catheter. The latter, upon being introduced into the bladder, yielded urine free from blood, but with all the characteristic features of pyelo-nephritis. It is obvious that in this case the complication of caruncle of the urethra led to an erroneous diagnosis, once more proving the fact that microscopical examination is a mere aid in diagnosis, and becomes valuable only by being combined with clinical examination.

Tumors of the bladder are of rare occurrence and usually give rise to temporary hæmorrhage, owing to the unstable or fluctuating condition of the walls of the bladder, due to the alternate expansion and contraction of that organ. Such hæmorrhages are, as rule, the first symptoms to draw the attention of the patient and the physician to a morbid condition of the bladder. I have recently had the opportunity of examining three specimens of tumors of the bladder, all of a villous type, and, therefore, will confine myself to the description of these three villous tumors, adding a report of a certain number of instances, in which the diagnosis of a villous tumor of the bladder was made by the examination of the urine only, without corroboration by surgical interference or post-mortem examination. (These researches I have conducted in the laboratory of Dr. Heitzman, in New York.)

To-day it is an acknowledged fact that but two types of villous tumor occur in the walls of the bladder, taking their origin from the mucous tissue of this organ. The benign type of villous tumor is termed *papilloma*, the malignant papillomatous or villous carcinoma. It is, indeed, a strange fact that this distinction, being of such vital importance, both to the pathologist and the patient, has been acknowledged only within the last fifteen years. Previous to this time every villous tumor of the bladder, without exception, was termed villous cancer.

C. Rokitansky speaks only of villous cancer of the bladder, admitting, at the same time, that it is a comparatively harmless affair, causing hæmorrhage, but scarcely ever producing infiltration in neighboring, or secondary tumors in distant, organs.

Kocher, of Berne, Switzerland, seems to be the first, in 1876, who described the form of tumor termed benign papilloma of the bladder. He was followed by Winckel, of Munich, in 1877, and by Alexander W. Stein, of New York, in 1881.

Lücke, of Berne, in 1869, made the following statement:[1]

"Papilloma of the bladder, or what is ordinarily designated cancer of the bladder, deserves special mention. This disease of the mucosa of the bladder consists in a villous proliferation of the submucous tissue which sends out long ramifying villosities, covered with a regular epithelium."

Although in this by no means rare variety of tumor of the bladder, secondary cancerous formations have not been observed, it was placed among the cancers mainly on account of its deleterious course. The diagnosis during life is easy when large villosities are voided with the urine, but a distinction between this form and the true carcinoma of the bladder is scarcely possible, since to both the uncontrollable hæmorrhages, the ulceration of the vesical mucosa, and the secondary diseases of the kidneys are common, as to all tumors of the bladder. Lücke says that polypous tumors of both the bladder and the urethra may exhibit a papillomatous growth, sometimes with considerable enlargement of the bloodvessels. His figure, copied from Demme, is intended to illustrate a papilloma, but in reality it exhibits plainly nests of epithelia in the connective tissue stroma, and, therefore, is a carcinoma.

Ultzmann and Hoffmann[2] give illustrations of what they call villous cancer, both with high and low powers of the microscope. Their drawings, however, correspond to an entirely benign papilloma, without any of the structural features that belong to cancer.

In 1887, Bizzozero[3] gave illustrations of a shred of connective tissue, and of flat epithelia, both single and in clusters, which no conscientious microscopist will dare to attribute to cancer.

Alexander Peyer[4] gives copies of plates both apparently from Bizzozero's and Ultzmann's illustrations, which he likewise considers diagnostic of villous cancer of the bladder.

The only author who has ever done justice to this topic is Alexander W. Stein. In his excellent treatise,[5] he sharply discriminates between benign papilloma and malignant cancer of the bladder. Plate I. of his book is a copy after R. S. Hudson,[6] exhibiting eight pedunculated papillomatous growths arising from the mucosa of the bladder. Some are as large as filbert-nuts.

[6] Polypi of the Bladder. Dublin Medical Journal, June, 1879.

In Plate II. he gives microscopical sections with both low and high powers. The explanation accompanying the figures drawn with high power, is especially remarkable for its clearness.

Hudson says:

"The thin-walled capillary vessels of irregular diameter may be seen coursing through the growth, the whole surface being covered with columnar or polygonal epithelium. The epithelium is, however, on the surface, *homologous*, not within the subjacent connective tissue, *heterologous*, which is characteristic of epitheliomatous growths."

Sir Henry Thompson, in a lecture[1] on "Tumors of the Bladder," states that:

"Until recently, most vesical tumors were supposed to belong to that class of growths roughly indicated as 'cancerous.' And, besides these, a single species was familiarly recognized under the term villous, although by some this was also relegated to the preceding class, as 'villous cancer,' without any warrant, however, for doing so. It was well known to be a bleeding tumor, which sooner or later produced a fatal result by its single irrepressible function of continuous bloodletting. This so-called 'villous growth' is, in fact, of all varieties, that which most commonly affects the bladder, under the name of papilloma."

In his classification he describes the following forms of tumors of the bladder: 1, mucous polypus; 2, papilloma; 3, fibrous papilloma; 4, myoma; 5, epithelioma; 6, scirrhus.

"The rarest of all is the dermoid tumor, which has been, on two or more occasions, met with in the bladder."

He also describes a class of tumors which "appears to be best indicated by using the term 'transitional' to describe it, as, perhaps occupying a place between papilloma and a formation of malignant type, sarcoma."

Mr. Gilbert Barling,[2] in a paper on "The Surgery of Tumors of the Bladder," in speaking of the classification of tumors, says:

"Hitherto there has been the greatest confusion, and nearly everything has been termed villous or cancerous, without any definite meaning being attached to either word. To many surgeons it will, I believe, be a surprise to learn that a very considerable number of these tumors are innocent. Examination of the records of nearly 300 cases show that about half of them were innocent tumors, the exact condition of nearly all being verified by microscopical examination."

"Amongst the innocent tumors papilloma is by far the most common, as it more than outnumbers all the rest put together. Of the malignant tumors two-thirds are carcinomas, and the remainder sarcomas, but it is a singular fact that until the last few years the existence of sarcoma of the bladder was ignored or denied.

"Carcinoma of the bladder is commonly of the squamous variety or epithelioma, but the alveolar growth does occur, and may be termed clinically either encephaloid or scirrhus."

He defines the term "villous" as merely descriptive, and not applied to a definite species.

[1] British Medical Journal, January 7, 1888.

[2] Birmingham Medical Review, May, 1888.

In the *British Medical Journal* for July, 1888, Mr. Barling described a case in which he removed a scirrhous carcinoma from the bladder of a man sixty years of age.[1]

The tumor which furnished the specimens for my own research appeared to be about the size of a child's fist. It was removed by supra-pubic cystotomy from the posterior surface of the bladder of a man forty-five years of age, the patient dying, several days after the operation, from septic peritonitis. The tumor was attached to the submucous tissue by means of a broad pedicle, and exhibited all over the surface a marked cauliflower-like appearance. After hardening in chromic acid, a portion was embedded in celloidin and cut in different directions. Low powers of the microscope sufficed to establish a diagnosis of papilloma (Fig. 1).

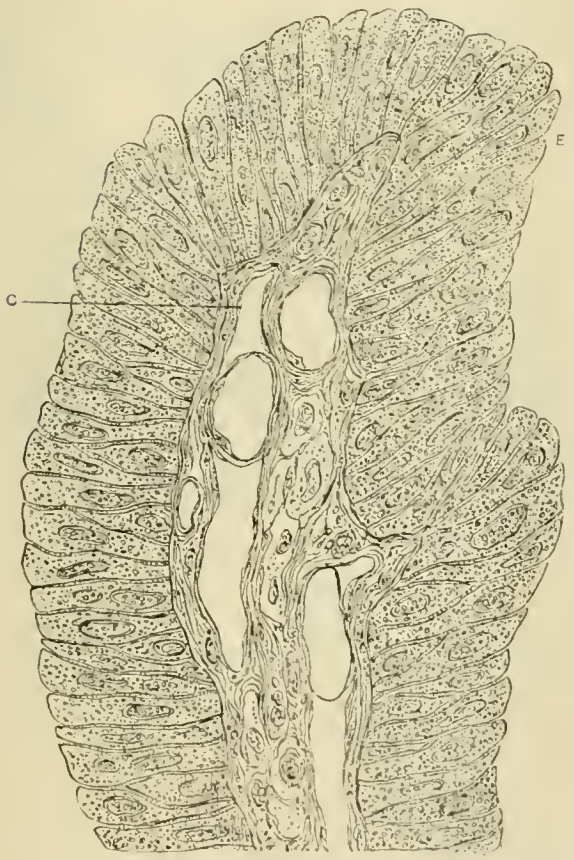
different directions, so that in one and the same specimen we observe longitudinal, transverse, and oblique sections of villi. This connective tissue is supplied with a large number of bloodvessels, mainly capillaries, but also many venous vessels were found, especially in the broad pedicle of the tumor. Toward the summits of the villi these vessels formed loops, often visible only in transverse sections.

The connective tissue is covered by a so-called stratified columnar epithelium of rather exceptional breadth. Most of the papillomata that have thus far been described, had a coating of cuboidal or short columnar epithelium arranged in a single layer.

Higher powers of the microscope give an insight into the minutiæ of the tumor (Fig. 2).

Fig. 2.



Papilloma of bladder. Longitudinal section of villus. × 500.
C, myxo-fibrous connective tissue with numerous and wide capillary bloodvessels
E, stratified columnar epithelium.

The connective tissue is neither purely myxomatous nor purely fibrous, but a combination of both, known as "myxo-fibrous." The network of this tissue is made up of delicate bundles of fibrous connective tissue, in the meshes of which we see protoplasmic bodies varying in size and shape, but nowhere very numerous.

The capillary bloodvessels are conspicuous by a pronounced adventitial wall of fibrous connective tissue, such as we often meet with in myxomatous or myxo-fibrous tissue, more especially of tumors. The endothelial coat of the vessels is marked by large nucleated endothelia, a rather common feature in newly formed bloodvessels generally. At the periphery of the connective-tissue formation there is a faintly marked layer, the "structureless or basement membrane." The covering epithelia are columnar of a rather unusual length, and stratified by the interposition of nucleated wedges between the points of approximation of the epithelia. The nuclei are vesicular, and, corresponding with the protoplasm around the nuclei, are finely granular. The cement substance between the epithelia is extremely narrow, and traversed by rather indistinct thorns.

All papillomatous growths of the bladder give rise to repeated, sometimes even dangerous hæmorrhages. The reason for this is obvious, when we consider the alternate contraction and expansions of the walls of the bladder, as well as to the currents and whirlpools created in the urine in its expulsion from the bladder.

We can easily realize that delicate shreds of the villosities may be torn off, either with their covering epithelium *in situ*, or detached. The epithelia alone cannot have a great diagnostic value, since they vary so much both in size and shape. The connective-tissue shreds, on the contrary, if voided with the urine in large quantities, are of positive diagnostic value, owing to their ramifying or cauliflower-like configuration, and their richness in bloodvessels, which are either filled with blood corpuscles or empty.

I wish to draw attention particularly to two cases in which hæmaturia was present, together with numerous branching shreds of connective tissue, rendering the diagnosis of papilloma highly probable. In neither of these cases was a post-mortem examination obtained, and for this reason the diagnosis did not go beyond the probability of the presence of papilloma of the bladder.

One of these cases was that of a man, of about fifty years of age, who, after many years of ailment from hæmaturia, died from exhaustion. In this case the villi were characterized by coils at their ends, somewhat resembling the tufts in the cortical substance of the kidney. Such tufts are not infrequently seen in papillomata of other organs. Possibly, however, they may be attributed to the coiling of the apices of the villi, caused by the whirl in the escaping urine (Fig. 3).

The detached epithelium in this case was cuboidal, somewhat resembling that of the pelvis of the kid-

ney, and, therefore, of no diagnostic value whatever.

The second case was that of a man, aged thirty years, who by previously repeated hæmorrhages was much exhausted. The shreds voided in this instance were not striated or fibrous, but either single worm-like granular masses, or masses of remarkable shapes, with many ramifications.

All these peculiar formations exhibited the structure of protoplasm, lacking basis substance. In various portions were seen numerous, small vacuoles, possibly the spaces, in which fat globules had been imbedded. (See Fig. 4.)

In this second case, some of the shreds so closely resembled the filaria sanguinis hominis that, at first sight, the possibility occurred to me that we had to deal with hæmaturia from such a parasite. But the ramification of these shreds, and the distinct fibrous structure of some of them, rendered the presence of a papilloma of the bladder more probable. The urine showed in addition numerous red blood-corpuscles in all stages of development, also a number of pus corpuscles, kidney epithelia, and granular casts, which features proved the presence of croupous or parenchymatous nephritis, as a complicating

disease, probably dependent upon the presence of a tumor of the bladder. Unfortunately nothing could be learned in regard to the fate of the patient.

I know of an instance in which beautiful ramifying connective-tissue shreds were found in the urine, together with a large amount of blood.

The diagnosis was obviously papilloma of the bladder. The hæmaturia ceased shortly after, and the patient died in about eight months of an intercurrent disease. At the post-mortem examination the mucosa of the bladder was found smooth and free from any tumor. This, of course, does not prove that the diagnosis was incorrect, but rather that a small papilloma attached by a slender pedicle, may have been completely torn away with the result of a complete cure.

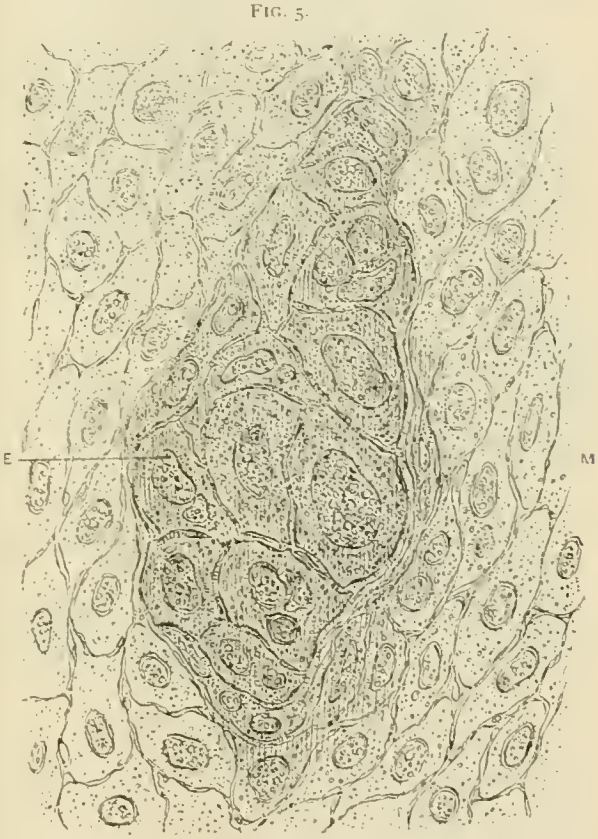
The second typical form of villous tumor of the bladder is the villous cancer. Alexander W. Stein, in his above-quoted study on tumors of the bladder, distinguishes four varieties of carcinomata, viz., epithelioma, encephaloid, villous cancer, and scirrhus, which, as he believes, are enumerated in the order of their frequency.

From my studies, I must take exception to the nomenclature of Dr. Stein. Villous cancer is not a distinct species, but merely a sub-variety of either epithelioma or medullary cancer, which latter form Dr. Stein designates by the rather obsolete name of encephaloid. Whether or not scirrhus ever assumes the shape of a villous tumor I am unable to say, since I have had no such case under personal observation. But I am positive that both epithelioma and medullary cancer may, under certain conditions, assume a villous appearance on their surface. In other words, a villous cancer is either an epithelial or a medullary cancer exhibiting the peculiar cauliflower-like appearance so characteristic of papillary tumors in general. It is quite possible that such villous carcinomata start originally in the form of harmless papillomata, gradually assuming the characteristics of cancer, as has been suggested by Kocher (loc. cit.). Obviously the mode of growth and the loop-like arrangement of the capillaries at the periphery determine the villous character of the tumor, which as such is by no means essential to the pathology and clinical course taken by the growths.

I have seen and studied cancer shreds which were voided with the urine in two cases. One was that of a woman sixty-two years of age, the other was that of a man fifty-six years old. In the first case microscopic examination proved the shreds to have sprung from an epithelioma; in the second case they came from a so-called medullary cancer of the bladder.

The shreds in the first case varied in size from the smallest branching or tree-like masses just discernible with the naked eye up to lumps half an inch long and one-quarter of an inch in diameter. The thinnest shreds being placed under the microscope, exhibited a number of detached epithelia of both the flat and cuboidal varieties. The main mass was made up of a delicate myxomatous or myxo-fibrous tissue, in which there were embedded numerous nests of flat, so-called dermoid epithelial cells disposed in the form of pegs and rows. The concentric arrangement of the epithelium was marked in but a few places. Higher powers of the microscope revealed the characteristic epithelial structure of the pegs, the epithelium being supplied with one or several coarsely granular nuclei, evidently in an active process of so-called indirect division. The epithelial pegs and rows were surrounded by a rather regular myxomatous tissue (see Fig. 5).

Fig. 5.



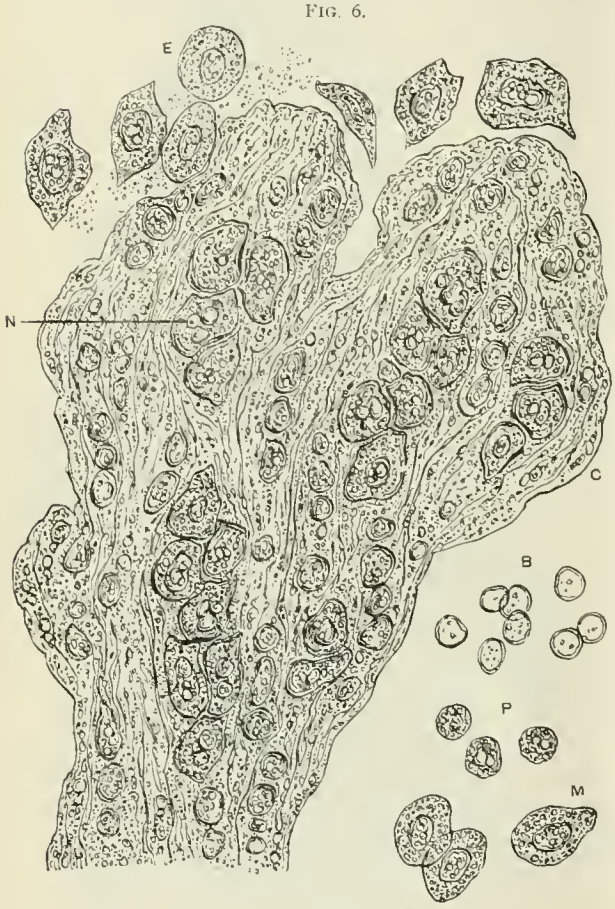
Villous dermoid cancer of bladder, so-called epithelioma, × 500
E, epithelial nest.
M, myxomatous connective tissue.

At the borders of the pegs the transitional forms could frequently be seen, indicative of a transition of connective into epithelial tissue. This transition was established either by a coarse granulation of both the protoplasmic bodies and the basis substance of the myxomatous tissue, leading to a transmutation into epithelium, or so-called myeloplaxes, multinuclear protoplasmic bodies of considerable size were

seen, which, by the appearance of new cement substance, seemed to furnish the material for future epithelial pegs. Dr. A. W. Johnstone,[1] of Kentucky, has described this mode of formation, as the rule, in the transition of lymph tissue into secondary cancer.

My second case was a medullary cancer, showing cauliflower-like or pointed excrescences upon the numerous though small shreds voided with the bloody urine (see Fig. 6).

FIG. 6.



Villous medullary cancer of bladder, × 500.

N, epithelial cancer nest.

C, connective tissue reduced to protoplasm and crowded with so-called inflammatory corpuscles.

B, red blood-corpuscles.

E, covering epithelium of tumor.

M, epithelium from either the middle layers of the bladder or from the surface of the tumor.

In this instance the connective tissue was devoid of myxomatous or fibrous structure, but was for the most part transformed into an uniformly granulated protoplasmic mass, holding a large number of so-called inflammatory corpuscles and numerous irregular epithelia, mostly arranged in small nests. This type of cancer is justly considered the most malignant of all. Unfortunately I am unable to give clinical details as to the subsequent history of either of these patients.

Villous cancer of the bladder has in times gone by always been considered rather mildly malignant, being instrumental in producing hæmorrhages, but not causing an infiltration of the contiguous tissues or secondary formations in distant organs. This view can no longer be maintained, since we know that there are two varieties of villous tumors, the benign papilloma and the malignant carcinoma. Papillomata may undoubtedly remain harmless so far as their pathology is concerned, though they may destroy life rather slowly by repeated hæmorrhages. Cancer, on the other hand, impairs the constitution by the loss of blood, as well as local growth and infiltration of the adjacent tissues. Further researches of tumors, positively diagnosed to be cancerous, will be required, in order to settle the question, whether primary cancers of the bladder do not cause the growth of secondary tumors in distant organs, as has been maintained by the older pathologists.

To-day, since electric cystoscopy has attained such a marvellous degree of perfection, the clinical diagnosis is much facilitated after the microscope has drawn attention to the presence of a villous tumor in the mucosa of the bladder. By this means the site, size, and configuration of the tumor may be readily determined in the living patient. The chances of successfully removing such a tumor by anterior cystotomy are likewise much more favorable than they were some twenty years ago, when antiseptic surgery was unknown to the operating surgeon.

[1] Microscopical Morphology, by C. Heitzman, 1888.

ELECTRICITY IN A CASE OF FÆCAL IMPACTION.

With Notes on Solvents for Fæces.

BY GUY HINSDALE, M.D.,

ASSISTANT PHYSICIAN TO THE PRESBYTERIAN HOSPITAL, AND TO THE ORTHOPÆDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES.

IN a case of constipation with periodic impaction that about eighteen months ago came under Dr. Weir Mitchell's care, such gratifying results were obtained that the following account of it may be of use to the profession:

The subject, a lady, about fifty years of age, for nearly fifteen years had been greatly annoyed by impactions of fæces. No very alarming symptoms had ever been brought on, and it was found that the hardened lumps would come away if the patient remained in bed several days. Many of these lumps showed evidences of having been weeks, and even months, in the intestine.

There seemed to be a particular place where these masses became lodged, side-tracked, as it were, for upon their final passage they could be readily distinguished from the accompanying excretion, the latter being comparatively soft.

A physician who had been previously consulted at one time introduced his hand and a portion of his forearm into the bowel, but did not discover any stricture. Dr. Mitchell considered the difficulty to be due to atony of the muscular coat of the intestine, and advised the use of electricity locally applied, and massage of the abdomen and of the body generally. In addition, the patient was to take a laxative pill and a tablespoonful of glycerin internally three times a day.

I had a special form of electrode made, consisting of a polished steel bougie two inches long and five-eighths of an inch in diameter, with blunt convex extremities. This was screwed to a flexible copper rod which was plated and insulated, and provided with a screw for attachment to a handle. This made an instrument sixteen or seventeen inches long.

About eighty applications of the faradic current were made, in which the instrument was usually introduced sixteen inches. As a rule, no great difficulty attended its passage, although it was not easy to pass the flexure of the rectum, especially if the fæces had collected, and it was generally possible to tell when the bulb passed by these lumps, which were lodged usually eight or nine inches from the anus.

Not the slightest injury was done to the intestine by the passage of the instrument. Sometimes flatus was forced backward along the bowel, causing momentary distress like colic, but otherwise no pain was experienced. A broad electrode, six by five inches, was applied at different places over the abdomen, and a moderately strong faradic current used for about half an hour daily. The internal electrode was withdrawn gradually, so as to influence directly the entire calibre of the bowel within its reach.

Injections of glycerin were tried without giving a satisfactory result; only mucus came away. Laxatives were abandoned later in the treatment of the case, and strychnine internally and hypodermically was resorted to, together with belladonna. Both Dr. Mitchell and the patient, however, were confident that the greatest improvement was made by the electricity, and at the end of treatment she found herself able to go about with freedom, without the least inconvenience from impactions, and is now in a better state of general health than for many years.

At Dr. Mitchell's suggestion, I made some experiments with the scybala passed from the bowel that I think are worth recording. Some of the smaller lumps of fæces about ¾ inch by ½ inch, selected as nearly alike as possible and in a state as when passed from the bowel, were put into several different fluids, to test the readiness with which they might soften, viz.:

I. Pure water. At the end of one week showed softening of the fæcal mass and discoloration of the water, the lump being at the bottom of the glass. In two weeks it was broken down and the water much discolored.

II. Pure glycerin. In one week no discoloration; the lump floated. In four weeks no perceptible change, excepting very faint discoloration of the fluid.

III. Aromatic sulphuric acid ʒj, water ʒvij. In one week considerable softening, great discoloration; lump sank; offensive. In two weeks great discoloration and softening.

IV. Cod-liver oil. In three weeks little, if any, change. In ten months no change beyond slight hardening of the mass and diffusion of the coloring matter.

The following experiments were made with a large egg-shaped mass, which was squared so that its surfaces were perfectly fresh. It was then cut into sections each about ¾ inch by ½ inch by ½ inch.

V. Pure water. On the first day the mass was at the bottom of the glass, and some tendency to discoloration and softening was noted. The softening was greater in one week. In two weeks it was crumbling, and fell to pieces on being disturbed.

VI. Lime water. In one day more softening and discoloration than in V. In one week it was quite soft, and in two weeks it crumbled, and on shaking was thoroughly disintegrated. This solution seemed to have the greatest softening action.

VII. Glycerin. In two weeks the lump seemed hardened. The color was diffused through the glycerin.

VIII. Tartaric acid, gr. v; water, ʒj. In the first day discoloration of the solution was noted. In two weeks the lump was still intact.

IX. Tartaric acid, gr. x; water, ʒj. In one day this showed the most discoloration of any of the fluids. No softening in two weeks; its shape was intact, but it could be disintegrated by pressure.

X. Glauber's salt, gr. xx, to fʒj of water. In one week the color was diffused and softening had commenced. After eighteen days the mass still retained its shape.

XI. Glauber's salt gr. xl to fʒj of water. Result the same as in X.

XII. Rochelle salt gr. xx to fʒj of water. In one week more softening than in X. and XI. In eighteen days well disintegrated.

XIII. Rochelle salt gr. xl to fʒj of water. Still more softening than in XII., and thoroughly disintegrated in eighteen days.

XIV. Soap solution gr. xx to fʒj of water. Not so much disintegration as in XII. and XIII.

XV. Soap solution gr. xx to fʒij of water. About the same result as in XIV.

The conclusion from these trials would seem to indicate that an alkaline solution, like lime water, or solutions of Rochelle salt, would be most likely to soften scybala; that oils and glycerin harden them, and that a weak acid solution chiefly affects the coloring matter.

ABSCESS OF THE CORNEA.

BY H. F. HANSELL, M.D.,
OF PHILADELPHIA.

THE symptomatology and pathology of abscess of the cornea may be found in every text-book on diseases of the eye, are well known and accepted, and a review of them in this paper may with propriety be omitted. Differences of opinion among eminent practitioners exist, however, in relation to the therapeutics, and may well invite further discussion.

The results of some clinical investigations pursued by me during the past year have shown:

First. That eserine is superior to atropine.

Second. That cocaine is a symptomatic remedy only, and, when long continued, is injurious.

Third. That the Saemisch operation is, in most cases, inferior to a simple division of the abscess.

To de Wecker should be ascribed the merit of repeatedly bringing eserine to the notice of the profession, and of urging its use in corneal affections. His followers have been few, and eserine has not attained that place in ocular therapeutics to which it is entitled. I have frequently prescribed it in abscess and deep ulcer, and have never regretted it. On the contrary, I am convinced that eyes have been saved, which under mydriatics would have been lost. The case described below, which is one of many, is a fair illustration, as eserine was used after other remedies had failed.

Two objections are urged against this drug: First, that the danger to vision, on account of the small pupil produced, is increased. This objection is just, and should be considered. Care must be taken that the contraction of the iris and ciliary muscles does as little damage as possible. To guard against permanent closure of the pupil and constant spasm of accommodation, instillations of eserine should be alternated with instillations of atropine, or the former may be used by day and the latter by night. These two remedies are therapeutically compatible, and, when employed in the same case with a full understanding of their effects, they give the best results. If, however, the abscess threatens to destroy the vision, the possible danger from posterior synechiæ and pupillary membrane should be risked. It is then a choice between two evils.

The second objection is that headache follows the use of eserine. This is invariably observed, yet, in my experience, it has not proven a real obstacle. When eserine is recognized as the cause and explained to the patient, the importance of the headache vanishes. The pain is not intense, and subsides in from one to two hours, and when, exceptionally, it interferes materially with the patient's well-being, the strength of the solution may be decreased. Stronger solutions than two grains to the fluid-ounce are not advisable.

The writer protests against the common practice of prescribing cocaine in abscess and other severe corneal affections. As a remedy, cocaine has no place in the therapeutics of the cornea. It is deservedly held in high esteem as an anæsthetic for the surface of the eye, and as an aid to atropine and other mydriatics in dilating the pupil. It is a well-known fact that it destroys the anterior epithelial surface of the cornea, and this occurs when used in weak as well as strong solutions. If applied but a few times, the epithelium is afterward restored, and the eye suffers no damage. If, however, the applications are frequently repeated, superficial ulcers and opacities result. The momentary relief from photophobia or pain cannot be advanced as a sufficient reason for its use in face of the undeniable fact that this very relief is obtained at the expense of the membrane already diseased. It needs no argument to prove how pernicious this action must be in those diseases which are caused by loss of epithelium and destruction of underlying tissue.

Operative interference should, in the opinion of the writer, be limited to a division of the anterior surface of the abscess and evacuation of the pus. The Saemisch incision is strongly advocated and practised by leading ophthalmic surgeons. This operation, however, has a serious disadvantage in that the anterior chamber is opened, the aqueous escapes, and anterior synechiæ or dislocation of the lens result as a direct consequence. It is advisable, and ought to be performed in those cases only in which perforation must occur or has occurred, and when the consequences of the operation are to be preferred to the greater evils of spontaneous or uncontrolled perforation.

The supplementary treatment may be dismissed with the briefest mention. In the formative stage: leeches, blisters, antiseptics, hot-water bathing, pressure bandages, laxatives, supporting measures, and liberal diet are required. In the convalescent stage: astringents to the lids, and cauterization of the ulcer with electricity or strong solutions of nitrate of silver.

Mrs. S., æt. thirty, an emaciated, delicate woman, completely exhausted from nursing a fifteen months' old baby. This exhaustion was in all probability the cause of the disease. She was too weak to leave her room, and so discouraged that she feared each day would be her last. The abscess was situated on the lower inner quadrant of the cornea, measured about four millimetres in diameter, and involved all

the layers of the cornea except the deepest. The epithelial surface was elevated by the pus. Hypopyon and unguis, neighboring cornea clear; iris dilated, but not adherent. The patient had been under treatment at a dispensary for two weeks before my first visit, and was using a solution of cocaine, atropine, and boracic acid locally, and iron and quinine internally. She had but little pain, and no photophobia. Vision for large objects only.

The abscess was opened and scraped on two successive days, the knife passing through diseased tissue only. Instillations of eserine every three hours by day, and atropine twice during the night; washing with Panas's fluid and frequent hot-water bathing were ordered. The baby was weaned, and the patient given twelve grains of quinine daily with milk punches and nourishing diet. In three weeks all inflammatory symptoms had subsided, leaving a thick white cicatrix three millimetres in diameter without adhesions of the iris.

The cure in this case might be attributed to the operations, and the drugs given a second place, but practically this claim would not hold. The abscess at the time of the incision could hardly be regarded as a collection of pus with well-defined boundaries. The surface was already elevated, softened, and non-resisting, and the pus had found its way into the lowest section of the cornea. Under the influence of the eserine, it must either have been absorbed, as part of it undoubtedly was, or driven to the surface by pressure against each other of the layers of the cornea excited by the eserine.

A CASE OF TREPHINING FOR TRAUMATIC EPILEPSY.

By KNUT HOEGH, M.D.,
of Minneapolis.

H. D., thirty-one years old, born in Norway, farm laborer, first seen November 4, 1889. He gave the following history, which was confirmed by his three brothers who accompanied him. When about two years old was shot by accident with slugs, producing numerous wounds of face and neck, and one of the forehead over the left eye. Profuse hæmorrhage and severe convulsions immediately followed. The child recovered, the frontal wound suppurating for about six months. After this he enjoyed good health until he was between sixteen and eighteen years old, when he had several epileptic attacks, the first coming on when he was in bed asleep in the early morning. His first attack was followed by an acute illness of two weeks' duration, and of unknown nature. He was again well and free from epileptic seizures for several years, when they returned with longer or shorter intervals. They would come in a series of two or three seizures within twenty-four hours, sometimes by day, at other times by night, and then there would be weeks or months of immunity. When about twenty-three years old, he shot himself in the leg while hunting in the mountains and nearly perished from hæmorrhage. After this accident a condition of melancholia developed; he lost interest in his work, became morose, had delusions of persecution, etc., for which he was sent to an insane asylum. He was discharged in about five months and was perfectly well with the exception of one single epileptic fit. He emigrated to America when about twenty-nine years of age, and earned a living as farm laborer and woodsman, being a steady worker, only rarely and moderately indulging in alcoholic stimulants. But soon after his arrival here he became again subject to fits, which made their appearance with increasing frequency, so that lately he has had three or four every month. Simultaneously with the advent of the epileptic attacks he became subject to a constant headache, which to him seems to start from the left side of the forehead.

Upon examination of the quite strongly built patient, there are seen several scars on face and neck, and one quite large, somewhat depressed and irregular cicatrix one and one-half inches above the left supraorbital margin, nearly two inches to left of the mesial line. It seems to be attached to the frontal bone, is white and tender on pressure; no convulsions are elicited by irritating the scar. Careful examination fails to detect any lesion of internal viscera; urine contains no albumin; pulse 72. Patient has a stolid expression of face, answers questions slowly and with a certain hesitation; there is a marked contrast between him and his bright and intelligent brothers, one of whom has observed him during several attacks and states that they are ushered in by a cry, that they are accompanied by twistings of the body, biting of tongue, and foaming at mouth, but that they do not begin in any particular group of muscles. A maternal uncle and aunt are said to have been insane.

A very excellent physician who had seen the patient formerly had given him medical treatment without benefit, and had advised an operation.

The patient was admitted to St. Barnabas's Hospital, November 6th, and after a full bath, the anterior part of the scalp was shaved and covered by sublimate dressings. The operation was performed the next day in the presence and with the advice of Drs. Burnside Foster, W. A. Jones, the house surgeon Dr. E. Wood, and P. A. Aurues, medical student. A hypodermic injection of ¼ grain of morphine was given and chloroform was administered, while the scalp was washed with oil of turpentine, alcohol, and a 1 : 1000 sublimate solution in acidulated water. The surrounding parts were covered by towels wrung from corrosive sublimate solution; the operator's and assistants' hands had been carefully disinfected; instruments had been sterilized by boiling for twenty minutes; sponges, cloths, dressings, and operating gowns by steam of 212° F. for half an hour, needles and silk by one hour's boiling. A horseshoe-shaped flap with its base outward embraced the scar and surrounding tissue, and was carried down to the periosteum. After the flap had been reflected outward, it was seen that the external scar did not correspond to the scar in the bone, which had to be exposed by an incision running horizontally inward for two inches. The scar in the bone was vascular, rough, and somewhat

depressed. A one inch trephine was applied and easily cut through the unusually thin bone. On the inside of the bone disk was found firmly fixed an irregular piece of lead, the size of a small pea, and several smaller grains of lead. The dura mater was adherent around the disk, somewhat thickened and slightly adherent to the underlying brain, which seemed rather reddish. The longitudinal sinus was not encroached upon, but the falx cerebri was seen dipping down between the hemispheres. The dura was laid open by a cross-cut, which produced some hæmorrhage, a few strands of disinfected horsehair were put in for drainage, and the dura was sewed with antiseptic catgut. The removed bone disk, which had been kept in a warm sublimate towel, was freed from the adherent lead by means of a chisel and replaced in the opening. No antiseptic or other irrigation was used in the wound, the blood and bone-dust being removed with sterilized gauze. The wound was sutured, leaving an opening for the horse-hair drain, and dressed with iodoform, sterilized gauze, and a bandage.

The patient looked pale after the operation, but recovered well from the anæsthetic and there were no other untoward symptoms. The horse-hair drain was removed on the second day; there had been some bleeding. Sutures, removed the fourteenth day, were found dry, and union by first intention had taken place everywhere. In the evening of the twelfth and morning of the thirteenth and again on the twentieth day, there were slight epileptiform attacks. The headache had entirely disappeared. The patient left the hospital on the twenty-first day. He had been put upon twenty grains of bromide of sodium, and five grains of iodide of sodium *per diem*, which he has been taking to this day. He has had up to the present writing—forty-fourth day—no new attack. He looks brighter, more contented and livelier, than when first seen. The bone disk is firmly implanted in the hole in the calvarium, and around its margin is felt a slight thickening as of callus.

This case seems to confirm Lucas Championnière's statement that trephining, properly executed, is comparatively free from risk; it also exemplifies the utility of Macewen's plan of implantation of the bone disk. It is too early to judge about the therapeutic effect of the trephining, except that it has relieved the headache and done no harm.

CLINICAL MEMORANDA.

OBSTETRICAL.

A Case of Measles followed by Pneumonitis and Premature Labor in a Primipara.—On the evening of Sunday, December 1, 1889, I was called to see Mrs. D. F., a woman of about twenty-four years, in her ninth month of pregnancy. After an examination I found that she was apparently suffering from the premonitory symptoms of measles, two of her brothers having just recovered from that disease. She was very uncomfortable, with general prickly sensations; was at times in great pain through her limbs, and was constantly coughing. Temperature 103.5° F.; pulse 120. She was given a diaphoretic mixture and antifebrin, with directions to take the medicines alternately every half hour until she felt somewhat relieved. The next morning I found her considerably easier, cough less dry, and the eruption beginning to appear. Temperature was now 100° and pulse about 90. From that time until Tuesday evening she seemed better, and strong hopes were entertained that the disease would run its usual course. On Tuesday evening I found a decided change for the worse: cheeks flushed, cough again dry and hacking, with severe pain in the lower lobe of the right lung. Physical examination revealed dulness over this lobe, proving to my mind that pneumonitis had set in. Temperature 104.5° and pulse 124; breathing very short and labored. The case began now to wear a serious aspect, and I entertained grave doubts as to its termination. The patient was rolling in bed from one side to the other, the cough was intensely wearing, and caused severe paroxysmal pain in the abdomen. I expected from the severity of the symptoms that labor might set in at any moment; but she remained in this condition until Thursday night, when I found her still very restless, coughing severely at times, complaining of intense backache and bearing-down pains. The physiognomy in its concentrated expression of agony was such as I shall never forget. On examination I found the os well dilated; the liquor amnii had escaped probably during coughing; the head was well down. I gave her occasionally small doses of quinine. After an hour or so the pains, which had grown weaker, almost ceased, or, at least, became inefficient, and I advised the forceps. This was agreed to: the forceps were applied, and a few minutes after, the mother was delivered of a well-formed boy. The uterus did not immediately contract, and, fearing hæmorrhage, I administered a drachm dose of Squibb's ergot. This, together with vigorous manual manipulation, soon caused contractions, and in an hour the placenta came away. The patient was now given some strong coffee with two drachms of brandy. The child was somewhat spotted, as though he had gone through an attack of measles in utero; but certainly at the time of birth was well. The mother reacted well; but this was of short duration. Soon the fever and pain in the chest returned, and her life for the next five days hung in the balance. Her temperature ranged between 103° and 104.5°; the pulse was constantly over 120, very weak, and thready. By antipyretics and sponging the temperature was temporarily reduced, but soon rose again. She was given egg-nog and milk-punch as food, and, medicinally, carbonate of ammonium and digitalis, with antifebrin and quinine alternately. On the sixth day after labor the temperature fell from 104.5° to 101°, and the pulse to 100. After this it rose once or twice above this point, but it was apparent that the crisis was passed. She was now put upon iron, nux vomica, quinine, and digitalis.

There are several features in this case which probably assisted in the ultimate favorable result:

1. Holmes's dictum of beginning two hundred years before birth to attain a result might well apply to her—she comes from a sturdy, strong farmer's stock.

2. She had improved on this sturdy graft by out-door farm-work.

3. She was a person of very cool temperament, and never once uttered a complaining word.

4. She was well nursed throughout her illness.

5. She was given during the entire course of her sickness nothing but *milk* with, at intervals, egg-nog and milk-punch.

6. And, finally, her case was studied from day to day. Medical treatment was specially directed to save (1) any unnecessary exertion; witness the application of the forceps, the Credé method of delivering the placenta without effort on the part of the patient. (2) Care in preventing even the slightest loss of blood. (3) Keeping up the strength of the heart with digitalis, ammonium carbonate, and brandy when indicated.

Literature.—*Lusk*[1] says: Rubeola is an infrequent complication of pregnancy, but is serious on account of its becoming hæmorrhagic, producing metrorrhagia, fatal to mother and child. Pneumonitis is a very frequent and dangerous complication of puerperal rubeola. And, again,[2] pneumonitis is an infrequent complication of the pregnant state, but affects the course of the latter very prejudiciously. . . . The fatal character of intercurrent pneumonia is referred to coexisting hydræmia, and to the inability of the poorly nourished heart to restore the balance of a pulmonary circulation disturbed by the consolidation of lung tissue and by the consequent impermeability of large capillary areas. Pulmonary œdema, resulting from progressive cardiac asthenia, "directly influences the fatal issue."

Overisel, Michigan

MEDICAL.

Local Applications of Sulphur in the Treatment of Diphtheria.—In the local treatment of diphtheria situated *above* the larynx, I find it of great advantage to preserve the false membrane as long as it will remain in its place. The diphtheritic membrane answers admirably, after having first applied a non-irritating disinfectant over it, to retain the medicament used and to *dress* the diphtheritic spots in the mucous membrane beneath.

The false membrane may be disinfected by irrigating it with a solution of any of the soluble disinfectants. The medicament afterward applied to the diseased areas should be slow of solution or insoluble. I have found washed sulphur to act well for this purpose. It may be insufflated, or, as I prefer, applied with a wad of absorbent cotton wound on the end of a stick, or with a large camel's-hair pencil. If well packed into the meshes of the membrane, from three to five applications in the twenty-four hours are sufficient; twice during twenty-four hours will answer in mild cases. Patients old enough to express themselves frequently assert, soon after the sulphur has been applied, that their throats feel better. Probably the sulphur, while in the meshes of the moist, warm, false membrane, takes up oxygen and sets free sulphurous acid, thus keeping the part in constant contact with this powerful germicide.

Calomel, also, answers well, but it should be used with care, and a known amount applied each time, and the applications made less frequently than sulphur. The applications of either sulphur or calomel should be made after the patient has taken nourishment, so that the medicament may remain on and in the meshes of the membrane for as long a time as possible. Of course, this precaution need not be observed when the nasal passages are treated.

HOSPITAL NOTES.

ANEURISM OF THE POPLITEAL ARTERY. AMPUTATION OF THE BREAST. DOUBLE HARELIP. RETENTION OF URINE. NÆVI OF THE SCALP.

Abstract of a Clinical Lecture delivered at the Hospital of the University of Pennsylvania,

By John Ashhurst, Jr., M.D.,
Professor of Surgery in the University.

Dr. Ashhurst presented a patient with a moderately large, thin-walled aneurism of the right popliteal artery, associated with valvular disease of the heart, and described the symptoms of aneurism in general as those of a pulsating tumor in the position of a large artery, the character of the pulsation being expansile, and not simply an up-and-down motion, as in the case of a solid tumor. In the present case there was some enlargement of the superficial veins, due to the pressure of the tumor upon the deeper veins. In the treatment Dr. Ashhurst proposed first to resort to digital compression, and requested assistance from those of the class who were so disposed. But if in three or four days compression did not prove effective, he would abandon it and ligate the artery above the sac. Compression, he said, acts by lessening the blood-current which enters the sac, allowing this to contract and permitting laminated clots to form.

The next patient presented was a woman who had been in the hospital several months previously for a small ulcer of the breast, with a retracted nipple and considerable induration. Dr. Ashhurst at that time was not satisfied that the disease was cancerous, and after the use of adhesive straps and careful dressing the ulcer healed. A few weeks later, however, ulceration returned, accompanied by considerable pain, and, as he now believed the breast to be in a pre-cancerous stage, he proposed amputation. The retraction of the nipple he considered usually characteristic of scirrhus.

He began the operation by an elliptical incision above and below the nipple. The flaps were then dissected up, leaving no more fat than was necessary, and the dissection was continued around the tumor down to the pectoral fascia. He said that in removing a tumor it was desirable to avoid cutting into it, as, if the growth is malignant and is opened, there is a possibility that the cells will be distributed and form starting-points of new growths. After removing the mass he incised it and found it indurated, with a tendency for the cut surface to

become concave, the latter being due to the presence of yellow elastic tissue. He did not open the axilla, as there was no induration of the axillary glands. The latter procedure adds to the gravity of such an operation, often gives an unsatisfactory ultimate result, and impairs the future usefulness of the arm, as the cicatrix tends to bind the arm to the side. For this reason he believes that in the majority of cases more good will be done by not opening the axilla unless there is strong reason to think that the glands are involved. After the hæmorrhage had been controlled he made a small opening in the flap, through which he inserted a drainage-tube. He then closed the wound and applied an antiseptic dressing and bandage, stating that if oozing occurred a second bandage would be applied with more pressure. The dressing would probably not be disturbed for several days or a week.

The next patient was a baby with double harelip. When, as is unusual, the harelip is double, the portion between the two clefts, corresponding to the intermaxillary bone of animals, often projects, as it did in the case before the class. The protruding portion turned up and was attached to the columna of the nose, but there was no cleft palate. Dr. Ashhurst first separated the columna from the projection, and cut this away with strong forceps. This was followed by some bleeding, which was checked by touching with a Paquelin cautery. The columna was then trimmed into a triangular shape. An important point in the operation was to separate freely the lip from the bone on each side, so that the former might be drawn well forward without much tension. The edges of the clefts were then freshened, in a concave direction, so that the resulting cicatrix would be longer than the natural depth of the lip, the object of this being to prevent the formation of a notch as the scar contracts. To control hæmorrhage while the edges were being freshened the operator used spring clips. He then inserted the pins, passing them through the entire thickness of the lip, which he had found the most satisfactory method, and reinforcing them with several silk sutures, and the usual figure-of-eight. A small piece of cotton saturated with compound tincture of benzoin was placed over the wound, and over this a strip of adhesive plaster. The pins should be removed on the third day, but the sutures and figure-of-eight ligatures allowed to remain two days longer.

A man was then presented suffering from retention of urine, caused by urethral stricture. Dr. Ashhurst said that he would first try to pass a catheter, and if he failed in this would open the urethra through the perineum. As stricture always occupies that portion of the canal in front of the prostatic part, by opening the urethra at the apex of the prostate we are certain to get behind the stricture, which can be dealt with subsequently.

In the present case the patient was carefully covered with blankets, as it is important to prevent chilling; and Dr. Ashhurst began with an ordinary sized catheter, not expecting to pass it into the bladder, but to determine the seat of obstruction. The stricture was found to be quite anterior and would not admit the catheter. He then used a filiform bougie with a corkscrew-shaped end, which readily passed, and over this was threaded a tunnelled catheter. This passed down to and was arrested by a second stricture. A smaller tunnelled catheter was then substituted, which readily entered the bladder guided by the filiform bougie. The instrument was then tied in place, and in twenty-four hours it would be found that a larger bougie could be passed. The stricture would then be treated by gradual dilatation.

The next patient was a baby with two nævi of the scalp and others on different portions of the body. Those on the trunk were not sources of disfigurement and required no treatment. For the largest nævus on the head Dr. Ashhurst said that he would employ the quadruple ligature, ligation being the most satisfactory method of treatment, and rarely followed by unfavorable results. He has had but one death following ligation of a nævus —a child operated on at the Children's Hospital. The nævus was at the root of the neck close to the great vessels. After the operation the child was taken out by the mother, an intemperate woman. It died some time later, but it was not certain whether the result was to be attributed to the operation or to neglect.

The quadruple ligature is applied by two needles passed through the base of the tumor at right angles to each other, each needle having a double thread. The needles are then removed, leaving four threads. The ends of these threads are tied together so as to make a continuous ligature. The strain, of course, comes on the last knot, and it is this that accomplishes the strangulation of the growth. The last knot is tied slowly, so as to thoroughly constrict the mass. In a few hours the nævus will become black and a line of separation will form; the slough will then be thrown off and a granulating surface remain. To the smaller nævus on the scalp Dr. Ashhurst used fuming nitric acid, working it in with a small stick until a thick slough formed. This, when it separates, leaves a healthy surface.

MEDICAL PROGRESS.

The Induction of Premature Labor.—M. BOISARD has recently contributed an excellent paper upon the usual means employed to induce premature labor. Considering first the uterine douche, he gives it his unqualified condemnation, and believes that the process is one which should be absolutely rejected, being slow, unreliable, and dangerous. Before contractions can be induced, it is often necessary to use the douches three or four times daily for four or five days: often they fail entirely. Moreover, they act only because of the traumatism caused, or, in the words of the author, they are a sort of aquapuncture. Fatal accidents with the method have been reported by Tarnier, Simpson, Olshausen, and others. Pinard has made a number of experiments which show that gentle irrigation is absolutely powerless to provoke labor.

Among the mechanical agents used for this purpose the most usual are sponge and laminaria tents. If either is used, it should be the latter, as it is much more difficult to render sponge aseptic. Tents, however, have the disadvantage of slipping out of place, of dilating slowly, and, particularly with the laminaria, successively larger tents must be introduced. Their use should be confined to primipara in whom the os is small and rigid.

Puncture of the membranes, though infallible, is dangerous, slow, and inconvenient; often causes lesions

of either the uterus or fœtus, and favors procidentia and abnormal presentations. There are certain conditions, such as hydramnios, in which the method is useful to produce depletion of the uterus.

The author then discusses the use of bougies and balloons, methods which he terms "excitor" and "excito-dilator." The insertion of a bougie is the simplest and most easily applied of all methods, but acts very slowly, sometimes fails, and has in a few instances caused accidents, such as perforation of the membranes and wounds of the placenta. It is usually necessary for the bougie to remain in the uterus for three or four days to produce contractions. The balloon dilators of Tarnier or Champetier offer the most satisfactory method yet described for the induction of labor. Champetier's dilator is better than Tarnier's, being larger, of a better shape, and not distensible. It dilates not only the os, but the entire vulvo-vaginal canal. With this instrument the average duration of labor is from twelve to fourteen hours. The disadvantages of the balloon are that it is sometimes difficult to adjust, and that it may cause rupture of the membranes, separation of the placenta, pushing back and alteration in the position of the child or prolapse of the limbs or cord. In eighteen patients treated by the author, there were two cases of ruptured membranes, one of placental separation, and three of prolapse: none of the cases terminated fatally in mother or child. Notwithstanding these disadvantages, the use of the balloon is the most rapid, safe, and satisfactory of all methods for the induction of premature labor.—*Journal de Médecine de Paris*, January 19, 1890.

The Treatment of Ozæna.—Dr. Moure, in *La Tribune Médicale*, writes that in a patient suffering from ozæna, the general condition should be modified by the administration of iodine, arsenic, etc., and, if possible, by a residence at the seaside, which usually gives the best results. The local treatment consists chiefly in the use of irrigations, which should be abundant and at a temperature of about 85° F. The author commences treatment by using one pint of water containing five drachms, either of sodium chloride, sodium bicarbonate, or potassium chlorate. Immediately after this he uses an antiseptic solution, varying the antiseptic from time to time. The following may be used at the beginning of treatment:

℞.—Carbolic acid . . . 2½ drachms.
Glycerin . . . . 1½ ounces.
Alcohol . . . . 6 drachms.
Water . . . . . 5 ounces.—M.

One teaspoonful is to be added to one-half pint of warm water and used as an irrigation. After this solution has caused a disappearance of the characteristic odor, usually within two weeks, it is replaced by a solution of chloral, resorcin, salicylic acid, sodium salicylate, or creolin. The latter is very irritating, and should be used in a weak emulsion, as follows:

℞.—Creolin . . . . 15 minims.
Alcohol . . . 2 drachms.—M.

One teaspoonful to a pint of tepid water. The following may also be used:

℞.—Aluminium aceto-tartrate 3 to 6 drachms.
Boric acid . . . 2 to 4 ounces.—M.

One teaspoonful to one pint of tepid water. After a time Moure uses the usual astringent solutions, and when the mucous membrane is dry the following:

℞.—Salol . . . . . 75 grains.
Vaseline . . . . 4 ounces.—M.

—*Journal of Laryngology and Rhinology*, February, 1890.

Rhubarb as an Anthelmintic.—According to the *Medicinisch-chirurgische Rundschau*, February, 1890, rhubarb, given in the following mixture, is an efficient remedy against oxyuris vermicularis, or thread worm:

℞.—Tincture of rhubarb . . 30 drops.
Magnesium carbonate . 3 grains.
Tincture of ginger . . 1 drop.
Water . . . . 3 drachms.—M.

This dose is to be administered three or four times daily.

Prescription for Dysmenorrhœa.—The following is recommended in the *Wiener medicinische Wochenschrift* for dysmenorrhœa:

℞.—Ext. of Indian hemp } of each ⅓ grain.
Ext. of belladonna }
Cacao butter . . . 1 drachm.—M.

Mix and make five suppositories. For five nights before menstruation a suppository is to be introduced into the rectum. [There certainly could be no risk in increasing the first two ingredients to twice the amount here given.—Ed.]

Resection of the Sternum.—At a recent meeting of the Hamburg Medical Association, Dr. Mening showed a patient on whom he had successfully performed resection of the sternum eleven months previously. For nearly four years a sinus had existed at the left border of the sternum, and constantly discharged cheesy pus. The entire bone was roughened. A free incision in the form of a cross was made, the greater portion of the sternum, including half of the manubrium, the gladiolus, and xiphoid process were removed, together with a large part of the costal cartilages. The carious bone was nearly four inches in length. Behind the sternum was found a large collection of cheesy pus, which was carefully cleared away. No disturbance of the respiratory organs was noticed after the operation, the wound healed satisfactorily, and the patient entirely recovered. —*Deutsche medicinische Wochenschrift*, February 6, 1890.

Application for Erysipelas.—In the local treatment of erysipelas, Professor Petresco employs carbolic acid in the following mixture:

℞.—Carbolic acid . . . 14 minims.
Collodion } . of each 6 drachms.—M.
Glycerin }

An Inhalation for Phthisis.—Professor Petresco, of Bucharest, uses the following for inhalation in pulmonary phthisis:

R.—Eucalyptol, Oil of turpentine, Creasote } of each 3 drachms.
Iodoform . . . . . 7 grains.
Ether . . . . . 75 minims.—M.

To be used in an inhaler.

Insufflation for Ozæna.—Cozzolino recommends the following powder for insufflation into the nostrils after the use of the douche in ozæna:

R.—Salol . . . . . 35 grains.
Boric acid . . . . 20 "
Salicylic acid . . . 3½ "
Thymic acid . . . 1½ "
Pulverized talc . . . 100 " —M.
—*La Médecine Moderne*, February 15, 1890.

Prescription for Gonorrhœa.—According to Jullien, the following is a good injection in the second stage of gonorrhœa:

R.—Mercury salicylate . . 1 grain.
Sodium bicarbonate . . 15 grains.
Distilled water . . . 4½ ounces.—M.

The Non-operative Treatment of Anal Fistula.—Guyon believes that fistulæ which do not give rise to distressing symptoms should not be operated on, but treated by palliative measures. The stools should be rendered regular and soft, and scrupulous cleanliness must be insisted upon. Internally, iron associated with the bromides may be administered according to the following formula:

R.—Bromide of potassium . . 75 grains.
Citrate of iron and ammonium 4 "
Syrup of orange . . 2 ounces.—M.

One tablespoonful twice daily.

After each stool the following suppository should be introduced into the rectum:

R.—Iodoform . . . . 2 grains.
Extract of belladonna . . ⅙ grain.
Cacao butter . . . sufficient quantity.
—*London Medical Recorder*, January, 1890.

The Abuse of Intra-nasal Treatment.—In the *Internationale klinische Rundschau*, December 28, 1889, Dr. Rethi, of Vienna, enters a protest against the indiscriminate use of the cautery and snare in the treatment of intra-nasal disease. Though neuroses arising from disease of the turbinated bodies may often be cured by operation, he has noticed that in some cases they are increased, and that reflex conditions may even be originated by the cicatricial tissue which forms after operations. He reports three illustrative cases:

The first, a woman of twenty-five years, suffering from hypertrophic obstruction, was treated by thorough cauterization. In about ten days she began to suffer from violent and increasing attacks of headache and paroxysms of sneezing. Cocaine temporarily relieved the attacks, but later the author was obliged to excise the cicatrices, after which the patient recovered.

The second patient suffered from attacks of vertigo following cauterization of the turbinals with chromic acid. This case also was relieved by removal of the cicatrix.

The third case resembled the first, and was cured in the same manner.

Puncture and Injection in Hydrarthrosis.—Dr. Falcoz has recently described, in the *Archives Générales de Médecine*, his method of treating hydrarthrosis by puncture and injection.

The diseased joint is first carefully washed with soap, then with sublimate solution, and, finally, with a mixture of alcohol and ether. A small trocar is used, having first been heated, washed with carbolic water, and oiled. The joint is then punctured, the synovial fluid evacuated, and the cavity is washed out with carbolic lotion 1 to 20, about two ounces being injected. This fluid is drawn off, the articulation emptied, and the carbolic solution again injected as before. The small opening made by the trocar is then occluded by means of a little collodion, and the limb is placed in a plaster dressing. At the end of two days the dressing is removed, and if a little of the fluid still remains, energetic compression is applied. It is very seldom that, after the second dressing and a little massage, the limb does not resume its normal state.

Dr. Falcoz summarizes his results as follows: Of sixteen hydrarthroses, thirteen resulted in complete and permanent cure; one of the remaining three had acute arthritis; one was treated with tincture of iodine; one was still under treatment.

Ten hydrarthroses were treated by simple puncture, and six by puncture followed by antiseptic washings. One of these hydrarthroses was particularly interesting, inasmuch as the simple puncture brought no favorable result, but the patient was completely cured by puncture followed by injection.

The conclusion seems justifiable, that the treatment by puncture and injection, inefficacious in cases of acute arthritis, always succeeds in chronic hydrarthrosis. Whether the hydrarthrosis originates under the influence of rheumatism or traumatism is of little importance; the essential factor is that there should be no acute inflammation in the joint, in order that, after having freed the articulation of its liquid, the irritating properties of the carbolic acid solution may prevent its re-formation. The operation, without being in the least complicated, exacts rigorous antiseptic precautions, neglect of which could easily transform a simple chronic hydrarthrosis into a purulent arthritis.—*Medical Chronicle*, February, 1890.

Ammonium Picrate in Malaria.—Dr. Studenezki has recently administered ammonium picrate, as recommended by Dr. H. M. Clark, in sixty-two cases of intermittent fever. He is of the opinion that the drug is valueless as a substitute for quinine, as it does not lower the temperature; but, instead of causing gastric disturbances, it relieves them if they exist. The author considers that the drug is indicated in patients suffering from apyrexial forms of malaria, and who have not become cachectic. He thinks it may be given with advantage on the afebrile days of an attack of ague. Six grains may be taken in twenty-four hours without unpleasant consequences.—*Lancet*, February 15, 1890.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, MARCH 8, 1890.

THE VALUE OF VIVISECTION RECOGNIZED BY ITS ENEMIES.

DURING the past week members of the Anti-vivisection Society have caused the arrest of Dr. Benjamin Shimwell, of Philadelphia, upon the charge of having been guilty of "wanton cruelty" to an animal upon which he demonstrated to a class of students a new modification of Senn's operation for wounds of the intestine. While realizing that their failure to obtain an anti-vivisection law some years since necessarily prevents any general onslaught upon scientific research, these persons evidently intended in this instance to make a test case under the Cruelty to Animals Act, with the view of impeding the labors of other more prominent members of the profession, and ultimately preventing in this manner all vivisection in Pennsylvania.

Having subpœnaed a large number of witnesses for the prosecution, several of whom were physicians, the enemies of original work felt quite confident of the success of their cause, and were represented by the son of Mrs. Thomas Earle White, one of the leading members of the prosecuting society. On the other hand, the friends of the defendant were represented by Mr. Ezekiel Hunn and Mr. Beck, the Assistant United States District Attorney. During the trial before Magistrate Eisenbrown, the circumstances of the operation in question were described with considerable detail by the witnesses called by the prosecution and, finally, Dr. Owen Wister and Dr. Garrettson were placed upon the stand as experts, to testify that the operation was needless and cruel. The first gentleman confessed that he was not an expert, but an ordinary physician, and allowed, as did Mr. White, at least for the sake of argument before the court, that vivisection was of value, but only when performed for the establishment of a fact, and not when an operation had already been frequently repeated. In the latter cases he thought that it was unnecessary cruelty, but in the present instance was unable to testify as to there being any pain inflicted, because he persisted that he knew nothing of the case in point. In reply to a question by Mr. Beck, he stated that he did not even know what operation was performed, or how to perform it if he did, and he also asserted, on cross-examination, that the most eminent scientific medical bodies in this country thought vivisection of value. The position of the witness was evidently that of the individual between the devil and the deep sea, and he did his cause more harm than good.

The next witness for the prosecution was Dr. Garrettson, who, as Dr. Shimwell's chief at the hospital, was in fact, if not in deed, an accessory to the act, in that he allowed his assistant to perform such work in the institution to which he was attached. Dr. Garrettson replied to the questions put by Mr. White and the defendant's counsel: "If the operation was performed twenty times a day for the benefit of the students at a college it would not be too much. Though," he added, with a smile, "I'd rather drop through the floor than say so, as I am opposed to the practice of vivisection." This from a prominent medical member of the Anti-vivisection Society, and one who a few years ago asserted, on the stage of the Hall of the Y. M. C. A., that he had "seen great tears roll down the dogs' cheeks as they smelt the walls spattered by the blood of previous victims," was received with applause by the persons present. So positive was Dr. Garrettson's testimony in favor of the defence, that the prosecuting attorney at once remarked that his case was lost, and that he confessed a defeat.

The court-room was crowded with prominent members of the profession, notable among whom were Drs. H. C. Wood, W. W. Keen, E. E. Montgomery, William H. Pancoast, H. E. Goodman, Frank Woodbury, John B. Deaver, and others.

Perhaps no better example can be obtained of two well-defined facts than the case just detailed. It illustrates the absurdity of a society made up of the laity, with a few medical men of peculiar ideas, attempting to dictate to one of the most learned, and at the same time the most kindly, professions in the world, as to what is or is not of value, and what is or is not unjustifiable cruelty; and it also shows that here, as in every instance where justice prevails, it is impossible for any ignorant individual or body of persons to interfere with the rights and privileges of an educated class simply because their opinions differ. But by far the most important result of this trial is to show one great dominant fact, namely, that because a man is an M.D., this is no reason for believing him a competent judge of all matters pertaining to medicine and surgery, and we congratulate Drs. Wister and Garrettson upon so frankly stating the truth concerning a branch of medicine with which they cannot be expected to be thoroughly versed, thereby avoiding disgrace to the medical fraternity, and affording an example to their deluded lay friends that they are not in every case experts and authorities.

Thus has one of the foolish freaks of perverted kindness once more killed itself by its own weapon, and we advise that the thousands of dollars spent annually in this silly crusade be devoted to the care and reformation of those of our own race who are sick morally as well as physically, and who are starving and freezing because of perversion of money from its proper humanitarian channels. Every one knows the limitations put upon the Society to Protect Children from Cruelty, and other similar institutions, because of lack of funds, and thousands of little ones die annually for the want of the breath of sea-air when the city's heat strikes them down, at a time when the anti-vivisection agitators are enjoying the mountains or sea, or at least spending money with an abortive and useless result, and direct harm to the future of medicine and surgery.

THE THERAPEUTIC USES OF IODOL.

Elsewhere in this number of The Medical News is published a paper by Dr. Cerna on the use of iodol, in which he details instances where the drug, when used internally or externally, did great good in diseases widely separated from one another. It has always seemed to us that the profession was too much inclined to pass this drug by as one which could only be considered a substitute for iodoform, and an almost useless addition to internal medicine. Some years ago Cervesato published the results obtained by him from its use in the treatment of scrofula and respiratory affections of a chronic type, and in the treatment of tertiary syphilis. He claimed that it does not readily produce iodism even when used in the dose of 15 to 45 grains a day, and that the stomach is not disturbed by its employment. Still further back Stembo wrote a paper asserting its value in diphtheria when it is applied locally to the affected area, using it alone, or in the form of a solution made up as follows: R.—Iodoli, ℈ss; alcohol, f℥ss; glycerini, f℥iiiss.—M. S. To be painted over the part.

The number of cases treated by him was seven, and every one recovered in from four to six days. The advantages he found consisted in its harmlessness, its lack of odor and taste, the painlessness of its application, as well as the avoidance of untoward after-effects.

In cases where a discharge from the middle ear needs a dry antiseptic powder iodol may be used in place of iodoform with success, and without the disagreeable smell of the latter drug. Under these circumstances Purjesz has found it useful in both the acute and chronic forms of this troublesome malady, as it always stopped the discharge in a few days in the acute attacks in his hands. When employed in the ear it may be applied once or twice a day, care being taken that it does not produce too much irritation in the part affected.

REVIEWS.

Historia de la Medicina en Mexico desde la época de los Indios hasta la presente. (History of Medicine in Mexico from the Times of the Indians to the Present Epoch.) By Francisco A. Flores. Three vols. 8vo., pp. 1640. Government Press Offices, City of Mexico, 1886–1888.

We hear so little from our sister Republic that we are sometimes inclined to believe that she is doing almost next to nothing with regard to medical or scientific matters in general. But we must confess that we have never examined carefully the position that Mexico occupies in the world of science, more especially in the world of medical science.

We forget, or perhaps we do not know, that the country has a great medical school in the City of Mexico, called the Mexican National School of Medicine (Escuela Nacional de Medicina), definitely established since the year 1833. At present it is magnificently fitted up with all modern improvements, and follows very closely in its teachings the French School of Paris. It has a fine faculty, most of whose professors have made their studies

in Europe, and, so far as the teaching is concerned, it has very fair facilities for the study of medical science. The city has quite a number of good hospitals, and to show that our professional brethren are not entirely idle, there are, we can positively state, a number of medical journals published in the capital, and a few in the different States of the Republic, which constantly bring to public notice well-studied and highly interesting cases, and also original articles on medical and allied scientific subjects.

Again, strange as it may seem, Mexico has (which, perhaps, no other country on the American Continent has, with the exception, of course, of the United States) a medical history, a history which will, no doubt, interest not only medical but scientific people at large, as it involves a period of several hundred years, and is intimately connected, in great part at least, with the social history of those highly intelligent ancient Mexican races which once inhabited "beautiful Anahuac."

We have before us a book on such a subject. It consists of three large octavo volumes of 1640 pages. It is the *History of Medicine in Mexico from the times of the Indians to the Present Epoch*, written in an interesting and pleasing style by Francisco A. Flores, graduate in pharmacy, and at present a student of medicine. It is preceded by a masterly preface from the pen of the eminent Mexican physician and philosopher, Dr. Porfirio Parra. The work is published by the Press Offices of the Mexican Government. The first two volumes have been ready since 1886, but it appears that the work was not given to the public until last year, when the third and last volume was printed.

On the whole, the work is a most interesting one, and reflects great credit upon its young and intelligent author, it being certainly a most valuable contribution, not only to medical literature in general, but also to American medical literature; and in order to do justice to Mr. Flores's able production, we propose to give subsequently a series of as careful reviews of it as possible, reviews which, we hope, will convey to our readers clear ideas of the book under consideration, and also about the interesting subject of which it treats.

Transactions of the Association of American Physicians, Fourth Session. Vol. IV., pp. 382. Philadelphia: W. J. Dornan, 1889.

Of the many volumes of transactions which annually come to this office, few, if any, contain so much of interest, or so valuable evidence of the progress of medicine as does this one. In vol. iv. we find papers by such well-known men as Minot, Stewart, Weir Mitchell, Henry, Musser, and Forchheimer, as well as a large number of others of equal rank and standing. Still others of the Association joined in the discussions of the papers as they were read, and this adds not a little to the usefulness of the book. One of the papers which, just at present, seems of unusual importance is that of Ernst on the danger of the transmission of tuberculosis by the milk of cows. The article by Dr. Busey on the effusion of chyle or chyle-like fluids into the serous cavities is also of great interest, while the article of Musser upon cancer of the gall-bladder and bile ducts is the most exhaustive account of this condition which has yet appeared, and is followed by a very valuable bibliography and list of cases, evidencing an amount of literary research which only those who have done similar work can appreciate.

Student's Aid Series. Vol. V.: Anatomy, Surgery, and Physiology. 12mo., pp. 236. New York: G. P. Putnam's Sons, 1889.

This volume is another of the series to which we have already called attention in previous numbers. It contains Aids to Anatomy, by George Brown, M.D.; Aids to Surgery, by the same author; and Aids to Physiology, by B. Thompson Lownes, M.D. As these important subjects are all considered in a duodecimo volume of 236 pages, it can readily be seen that no very great space can be given to any one of them, and in consequence the subjects are dealt with most superficially. Examination of the book shows, however, that far more is contained in it than one would imagine, and we doubt not that it may be of some service, particularly to the student who chooses, by the purchase of several similar books, to acquaint himself with all the necessary facts for the examination room.

Student's Aid Series. Vol. VI.: Chemistry, Forensic Medicine, and Toxicology. By E. E. A. Semple, M.D., and W. D. Hemming, M.D. New York: G. P. Putnam's Sons.

Aiming merely to outline, without elaboration or discussion, the teaching of one or several schools in the particular branches indicated, this volume can fairly claim to fulfil its purpose. Rarely rising to the dignity of text-books, the best realization of the object of such efforts demands that they clearly and precisely follow the views and system of one individual teacher. In endeavoring to become general in their usefulness, they are apt to be confusing so far as the necessities of the student preparing for his examination are concerned. For this reason, unless, by personal examination, he finds it corresponding sufficiently to the methods of his instructor, it would be unwise to recommend this work to the student in any particular school. As such works go, however, the volume is excellently compiled, its several subjects being carefully systematized, and its instructions stated clearly and briefly.

The book is divided into Inorganic Chemistry, Organic Chemistry, Legal Medicine, and Toxicology, the first two having been prepared by Dr. Semple, the latter two by Dr. Hemming. Although a foreign work, both compilers being residents of London, the differences in English and American laws are not sufficient to lessen the value of the chapter on Forensic Medicine, although most American teachers would probably hesitate to accept the classification of mental diseases and their discussion as given by Dr. Hemming.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 6, 1890.

THE EPIDEMIC OF INFLUENZA.

In the discussion of the Academy of Medicine, in which a number of well-known physicians of this city

participated, there was a pretty general agreement as to the main features of the epidemic influenza and the severity of the complications. The only note of discord was struck by DR. F. H. BOSWORTH, who declared that, although his practice was chiefly in diseases of the respiratory tract, he had not seen anything in his daily work which warranted the statement that there was an epidemic of influenza. By an epidemic of influenza, he understood one which affected a large proportion of the people in a community, and which was accompanied by a peculiar and clearly recognizable train of symptoms. Colds were not most common in cold weather, but when the temperature is moderate and the atmosphere laden with moisture. He felt positive that whatever increase in the number or severity of the cases of respiratory disease had been noticed, could be explained by the unusual climatic conditions which had existed, aggravated by the influence of malaria. He thought it was nearer the truth to say that the epidemic was one of break-bone fever.

These radical views were not shared by the other speakers, for, as Dr. Jacobi said, the histories of previous epidemics show that they often occurred when there were no such peculiar climatic conditions, and that they had not infrequently visited snow-bound coasts. This statement was corroborated by Dr. Kinnicutt's remark that in the western part of this country the winter had been unusually severe, and yet the epidemic had been quite as extensive there as here.

DR. A. JACOBI formally opened the discussion by reading a paper upon the phenomena observed among children suffering from the influenza, the prophylactic measures that should be adopted, and the remedies that were of service in the treatment of the severe forms, and of the complications.

Children had not been frequent sufferers from the disease, and this was quite possibly due to their being less exposed to the inclemency of the weather. When they were attacked, the fever was usually moderate, possibly owing to modern methods of combating it, and the bronchitis was quite general, accompanied by but little dyspnœa, and with the usual scanty expectoration of childhood. Headache was an almost constant symptom, and was diagnosed in infants by the contraction of the frontal muscles and the dazed appearance of the little sufferers. Convulsions were occasionally observed, as was also delirium in a few cases having high fever. Vomiting was often present; loss of appetite the rule; and diarrhœa not uncommon. Conjunctivitis had not been among the first symptoms, and otitis media had only been occasionally observed. When the disease was complicated by pneumonia, bronchial breathing and bronchophony, which are usually prominent signs in the early stages of pneumonia in children, were not readily obtained; and dulness developed very slowly. The cases were frequently complicated by other conditions, such as pleurisy with effusion.

It is only after the second year of life that influenza affects children in the way described; before that time, the locality of least resistance is the alimentary tract. It was noticeable that the injected throats which are so common when scarlatina and diphtheria are prevalent, were not observed during this epidemic. When the oral cavity suffered, the tongue became red, the papillæ elevated, and even the gums were affected. Dr. Jacobi had met with the scarlatinous eruption mentioned by many writers in only two cases—one in a child of two years, having a slight fever, and the other where the temperature was 104°, and the whole surface covered with the eruption. Herpes had been seen occasionally, but urticaria not at all. Neither had he observed the paralysis mentioned by Da Costa. Pains in the extremities were very frequent, and in one case, where the ankle was the seat of a chronic epiphysitis, the influenza caused a marked exacerbation of the trouble.

Relapses of influenza were not so often observed in children as in adults, possibly because of the milder type of the disease, but more probably on account of the avoidance of the premature exposure and exertion which so frequently caused a return of the disease in older subjects.

There can be no doubt as to the miasmatic origin of the influenza in many well-authenticated cases. Dr. Watson, in his *Practice of Physic*, published in 1871, gave a notable instance of this. A ship having arrived on the coast of Devonshire during the prevalence of a land wind, forty of the crew were taken ill within half an hour, and on the following day no less than one hundred and sixty were on the sick list.

As regards the spread of the disease, and the question of contagion, E. A. Parker, in Reynolds's *System of Medicine*, calls attention to a number of cases occurring in the last century, which were traced to direct contact. It has been noticed in hospitals, that patients in adjacent beds caught the disease first. The disease seems to be not only miasmatic, but also intensely contagious, with a very short period of incubation.

In the light of this knowledge, it seems wise to refuse such patients admission to general hospitals, and to consider carefully the advisability of closing the schools during such epidemics.

In the treatment of these cases, quinine in small doses was found beneficial; and acetanilide, antipyrine, and phenacetin all rendered good service; but of the latter class, phenacetin is the best on account of its less disagreeable effects upon the brain, heart, and skin. The gastric irritation is best controlled by the administration of resorcin, salicin, or the salicylates, it being remembered that for infants and children the doses of these remedies are proportionately large. The great danger of the disease is from prostration and heart failure; and in the cases where there is much gastric irritation, the debility is still further increased by the difficulty of nourishing such patients. Recourse must be had to rectal alimentation; and where heart failure is imminent, cardiac stimulants, such as musk and sulphate of spartein, must be boldly administered.

DR. W. H. DRAPER continued the discussion, limiting his remarks to the consideration of the complications and the sequelæ. The former were, like the symptoms, divisible into two principal varieties—1st, those included in sensory and motor derangements resulting from the effects of the materies morbi upon the cerebro-spinal system; and, 2d, those illustrating the manifold and severe lesions which the disease determines in the mucous membrane.

The former variety is characterized by functional disturbances of the cerebro-spinal system, and the latter by

more or less severe inflammatory processes in the respiratory and alimentary tracts.

The most serious complications of the respiratory tract have been bronchitis, broncho- and pleuro-pneumonia, and pleurisy. Bronchitis has been confined mostly to one lung, and the expectoration has not been very abundant. In catarrhal pneumonia the signs of consolidation have been delayed for some days after the subjective symptoms have suggested its presence. The pleuritic element has been unusually pronounced, and the pain has been widely distributed and very intense. In croupous pneumonia, the pulse-respiration ratio has been more disturbed and defervescence has occurred somewhat earlier than is usual. Resolution has been slow, and in many instances this has been found to be due to the presence of small empyemas.

One case which illustrated the tendency occasionally shown by this disease to spend itself on the alimentary tract, at first simulated typhoid fever, and, later, colitis; but inasmuch as two cases of ordinary influenza occurred in the same family with pulmonary symptoms, it seems reasonable to suppose that this case was one of the rare forms in which the pulmonary catarrh is supplanted by the intestinal lesion.

Dr. Draper had not seen any complications affecting the genito-urinary tract, and repeated examinations of the urine had not shown the presence of as much albumin as is common in other infectious diseases. Among the nervous complications may be mentioned neuralgias, which frequently make their appearance after the subsidence of the febrile and catarrhal symptoms, and are more or less periodic. They follow the course of the main nerve trunks and are aggravated by movement—two features indicating that the lesion determining them is a perineuritis.

Alcohol has been largely recommended both as a prophylactic and a curative agent; but from a study of cases, both in hospital and private practice, Dr. Draper had come to the conclusion that except in very moderate doses, it was decidedly detrimental. He had been very much impressed with the analogies presented by the influenza to other infectious diseases, and particularly to cerebro-spinal meningitis; and he thought the mucous catarrhs may perhaps be entirely due, as the cerebro-spinal symptoms are, to the effect of the poison on the vaso-motor system. This seems to be the only way to account for the great variety of the lesions and the sudden and overwhelming massive congestions.

Dr. F. P. Kinnicutt then took up the subject, dwelling more particularly, however, upon the marked suicidal tendencies evidenced in some cases, and the peculiarities of the pulmonary complications. A nurse in St. Luke's Hospital suffered from vivid hallucinations of sight for several days following the febrile stage of the influenza. A rather remarkable family group had come under his observation in which the first child taken sick had only a single convulsion, followed by a well-developed broncho-pneumonia with tardy convalescence; the second child had slight convulsions from time to time during the week following the onset of the disease; and the third child, an infant of eighteen months, with no other symptoms excepting moderate bronchitis, had severe and almost incessant convulsions for a week, and then died. Such remarkable disturbances are seen in but few of the infectious diseases.

Broncho- and primary lobar pneumonia have occurred with nearly equal frequency in both hospital and private practice; but the severity of the former in adults, with an unusually free capillary hæmorrhage, as shown by bright red blood in the sputa, and the frequency with which the latter variety has involved both lungs, show most clearly the influence of the influenza upon them. In a case of pneumonia which terminated fatally the autopsy showed a lobar pneumonia in the stage of red hepatization in one lung and evidences of broncho-pneumonia in the other.

The cases of influenza which have occurred in St. Luke's Hospital may be summarized as follows: 15 cases of lobar pneumonia, both lungs being involved in 4, with 7 deaths; 9 cases of broncho-pneumonia with 3 deaths. An examination of the hospital records for the preceding six months showed that out of 16 cases of lobar pneumonia only 3 involved both lungs.

Dr. M. A. Starr said that 42 per cent. of all the cases under his observation during the past six weeks had been attacked by the influenza, and then mental depression and peripheral nervous disturbances were pronounced. In many cases this mental depression amounted almost to a mild melancholia, and three of them had a decided suicidal tendency, associated with a slow pulse occasionally alternating with a very rapid one. In one case the pulse rose to 120 for periods of from fifteen to thirty minutes.

After certain epidemics chorea and poliomyelitis occur more frequently, and the movements of the former are temporarily increased in patients already suffering from the disease; but such changes had not been noticed in connection with the present epidemic. The pains of locomotor ataxia had, however, been perceptibly increased.

Dr. R. Guitéras, who had been fortunate in observing a considerable number of cases of the cutaneous variety, spoke particularly of these forms. From a diagnostic point of view, the most important variety was what he would classify as *Influenza Erythematosa*. He cited several cases of this in which there was a general blush of the body surface with rise of temperature, angina, reddened tongue, and other symptoms closely resembling scarlatina. Six cases were also observed in the New York Foundling Asylum. Apparently this form is most common in adult females. The eruption usually disappears within twenty-four hours.

In erythema the eruption is not punctate and is of a faint bluish-red tint; the tongue is covered with a heavy white coating; the papillæ are enlarged; and the skin is always moist. In scarlatina, on the other hand, the eruption is fine, punctate, of a scarlet color; the tongue is not so thickly coated and has a more distinctly strawberry appearance; and the skin is hot and dry.

Herpes labialis and miliaria have been occasionally observed, and Dr. J. H. Byron has noticed among the Italians at the New York Dispensary a peculiar bright red, coarsely papular eruption over the face, arms, and chest closely resembling erythema multiforme.

Dr. Burke has reported several cases of sore tongue, where the organ was large, red, hard, and so tender that pressure against the teeth was painful; the tongue "felt too large for the mouth," and was often allowed to protrude somewhat; the papillæ were enlarged and prominent, especially the group on either side of the

middle of the tongue. This peculiar condition usually made its appearance on the second or third day, and lasted for about one week. It was not an accompaniment of any particular type of the disease.

The number of deaths from influenza reported to the Board of Health during the past week were 121, of which number Dr. Guitéras investigated, with their attending physicians, 86 cases, with the following results: 33 from lobar pneumonia, 21 from lobular pneumonia, 13 from bronchitis, 4 from meningitis, and 15 from other diseases. Of the remaining 35 cases, the causes assigned on the death certificates were: Pneumonia 19, bronchitis 8, and other diseases 8. Of the 33 cases of lobar pneumonia, 28 occurred in men, only 4 being over fifty years old and only 1 under twenty years. Of the 21 cases of lobular pneumonia, 15 were in women; and of the 13 cases of bronchitis, 9 were also among women. Only 2 deaths were directly due to the influenza—1 in a debilitated Italian, sixty-one years of age, and the other a baby eight days old.

DR. A. L. LOOMIS commented upon the remarkable tendency of the cases of bronchitis in adults to become capillary, and said that when it did reach the finer tubes, a pleurisy was immediately established outside of and corresponding to the seat of the circumscribed capillary bronchitis. Convalescence was exceedingly tedious. It is remarkable that very few cases of capillary bronchitis developed into acute tuberculosis of the lungs.

At the Loomis Laboratory investigations were in progress with a view of establishing the existence of the peculiar bacillus of this disease, and many varieties of bacilli have been inoculated upon animals, but so far without success. He did not think that the lower animals were, as a rule, susceptible to this influenza.

In connection with the question of contagion, and the spread of the disease, it was interesting to note the success that had attended the quarantining of the Saranac Sanitarium for phthisical patients.[1] All connection with the outside world had been cut off, and not a single case of influenza had developed within that institution.

CORRESPONDENCE.

A HOMŒOPATHIST'S DEFENCE.

To the Editor of THE MEDICAL NEWS,

SIR: The time for vehement denunciation in scientific discussion has, or at least should have, long since passed. The unknown has so oft' been made plain, and the apparently impossible so frequently wrought, that the improbable dare not be thoughtlessly set aside. Medicine affords no exception. Ridicule and denunciation afford no argument against facts, and certainly they never can destroy truth, even though for a season they may retard its growth and development.

Thus ran my thoughts on reading an "An Ethical Question," by S. Solis-Cohen, M.D., which was honored by a place in a recent number of your journal. If I understand his article, he makes the following assertions:

First. There are those in the homœopathic school who implicitly follow Hahnemann, and there are others who, while they accept the law of similars as the law of cure, still do not accept Hahnemann's theories relative thereto.

Secondly. He asserts *his* view that to be a homœopathist one must accept all of Hahnemann's theories.

Thirdly. He asserts that Hahnemann rejected anatomy, physiology, semeiology, pathology, etc., and,

Fourthly. That consultation between the members of the two schools is practically impossible.

For the first and fourth of these assertions we will not ask time or space for a reply.

The second and third, however, are so glaringly false, that we desire, most heartily, to dissent.

To be a homœopathist does not of necessity involve a belief in, or acceptance of, any of Hahnemann's theoretical explanations. In fact, Hahnemann himself declares, in reference to theoretical explanations of the therapeutic law, § 28 *Organon*, "I attach but little value thereto."

Kepler accepted the Copernican system, but only to frame new and better explanations. In fact, the three laws known by his name have firmly established the law so imperfectly known to Copernicus. As well might the astronomer of to-day be denounced as a non-believer in Kepler's laws, because he rejects the erroneous fancies of that most astute observer, as to denounce the homœopathist who accepts the law, but rejects the theoretical explanations of Hahnemann. Nor would we reject Kepler's great laws because, that, under the influence of the faulty mechanical knowledge of his day, he evolved the theory of the vortices. Who will reject the Rudolphine tables because of the few errors they contained? Perfection is nowhere found.

Neither dare we require of Hahnemann faultless theory nor superhuman perfection. The law is true—the theories induced thereby, and even the results of man's application of the law, may abound with error. Our duty is to eliminate the error and develop the great truth expressed in the law. Blind adherence never has been, nor can be, yielded. With all honor to the founder of our school, we have been homœopathists, not necessarily Hahnemannians. Even in the copy of the *Organon* from which Dr. Cohen quotes may be read the following from the pen of Dr. Hering, one of Hahnemann's most ardent adherents:

"Whether the *theories* of Hahnemann are destined to endure a longer or shorter space, whether they be the best or not, time alone can determine; be it as it may, however, *it is a matter of minor importance*. For myself, I am generally considered as a disciple and adherent of Hahnemann, and I do indeed declare that I am one among the most enthusiastic in doing homage to his greatness; but, nevertheless, I declare also that since my first acquaintance with homœopathy (in the year 1821) to the present day I have never yet accepted a single theory in the *Organon* as it is there promulgated. I feel no aversion to acknowledge this, even to the venerable sage himself. *It is the genuine Hahnemannian spirit totally to disregard all theories*, even those of one's own fabrication, when they are in opposition to the results of pure experience. All *theories* and *hypotheses* have no positive weight whatever, except so far as they lead to new experiments, and afford a better survey of the results of those already made."

"Whoever, therefore, will assail the theories of

[1] See THE MEDICAL NEWS, February 15, 1890.

Hahnemann, or even altogether reject them, is at perfect liberty to do so; but let him not imagine that he has hereby accomplished a memorable achievement. In every respect, it is an affair of little importance."

Thus wrote Hering in 1835, yet he ever remained one of the most enthusiastic teachers of Hahnemann's law. The law we accept. Theoretical explanations of the law will be liable to change until science has become perfect.

The assertion that Hahnemann rejected the true teachings of anatomy, physiology, pathology, and diagnosis is absolutely groundless. In fact, in a paragraph just preceding that from which Dr. Cohen quotes in substantiation of his assertion, Hahnemann refers to "the meritorious work of many physicians in relation to the auxiliary sciences pertaining to medicine, such as the advancement of physics and chemistry, natural history in its different branches, and in that of man in particular, anthropology, physiology, anatomy, etc. He then especially declares, "I shall now only consider the practical part of medicine—that of curing." Can any unprejudiced reader require more explicit statement from Hahnemann, as to his reason for not further referring to these branches? His writings were directed to a profession supposed to be learned in such necessary matters; reference to them would therefore be unnecessary, save in so far as they were employed as foundations for erroneous theories. Any reader who will carefully peruse the introduction to the *Organon*, either in the original German, or in the Wesselhoeft translation, will readily see how different was Hahnemann's idea from that ascribed to him by Dr. Cohen.

The criticism in the first paragraph on page 433, vol. lv., of The News manifests either a lack of understanding, or an evident desire to misquote, on the part of the critic, for had he read, f. n. to § 7, *Organon*, he would have observed that Hahnemann recommended surgical procedures when necessary; he says, "extract irritating particles causing inflammation of the cornea," "avert the danger of a hæmorrhage, by exposing and ligating a wounded artery," "crush a vesical calculus," "open the imperforate anus of the newborn child:" while in § 13, Hahnemann speaks of "those forms of disease not belonging to manual surgery," and again, in § 186, he speaks of injuries to the body requiring mechanical skill, and refers to "extracting foreign bodies," "opening the cavities of the body to remove a molesting substance," as a tumor, "or to draw off effused or accumulated fluids," etc., etc. Evidence such as this shows most clearly that Hahnemann looked upon a thorough education in the collateral branches of medicine as essential, both to the development of correct judgment, as well as in rendering efficient aid to the sick. Hahnemann's opposition was directed against "the habit, wherewith so many physicians ambitious for fame have wasted both powers and time," "of weaving into so called systems, mere empty fancies and hypotheses regarding the internal nature of the life-processes, and of the origin of disease." The origin here referred to is not the *causa occasionalis*, which, he says, "It is taken for granted that every intelligent physician will search out and remove," but that hidden dynamic cause which is directly related to that all-pervading dynamis called the vital force.

That Hahnemann did not look upon this active force, or "dynamis," as independent of matter, will be evident to every reader of his essay on the "Mode of Propagation of the Asiatic Cholera," published in 1831, about a year before the fifth edition of his *Organon* went to press. Speaking of the spread of the disease through careless physicians and nurses, he says, "they take away with them in their clothes, on their skin, on their hair, and probably also in their breath, the *invisible* (*probably animated*) *and perpetually reproductive contagious matter* surrounding the cholera patient, and this *contagious matter* they unconsciously and unsuspectingly carry along with them throughout the town." Words of such import might well be attributed to a believer in the germ theory of to-day. While, however, Hahnemann acknowledged the necessary presence of matter, he, nevertheless, held to the view that such matter was necessarily imbued with a peculiar dynamis, through which it became endowed with potent virulence, just as to-day many view the bacteria and other micro-germs as but conveyers of poison—not the poison itself.

Again, Dr. Cohen asserts that Hahnemann discards all attempts at diagnosis. This is most certainly false; and for proof let me but refer to the careful diagnosis of "the genuine scarlet fever," as well as the differential diagnosis between it and the then existing "red miliary fever," falsely called scarlet fever, "Lesser Writings," pp. 479-483; also his remarks on "Asiatic Cholera," pp. 753-756.

In fact, he urged upon the profession the necessity for closer observation and more accurate individualization in disease, suggesting that class names should be used for convenience; he says, "we ought rather to say, a species of chorea, a species of ague," etc. Knowing that disease is constantly changing, new forms and combinations constantly arising, as instanced in f. n., § 73, *Organon*, he feared the misleading effect resultant upon the use of a specific name for such varied states. Hahnemann urges physicians to employ the "greatest care and systematic methods," and denounces "the loose and inaccurate methods in general use." Just here let me remark that in a letter written shortly before Hahnemann's death to Dr. Hering, he asserted the utility of pathology, if once founded upon a scientific basis.

The homœopathic school still adheres to the grand and comprehensive law discovered by Hahnemann, which is, and ever will remain, the only direct law of cure. We do not deny that palliation of diseased states may be secured through either of the other principles of drug action, and thus nature be imperfectly helped to a cure. We claim, however, for the law of similars, that under it we possess the speediest, safest, and most certain means whereby cure may be effected.

Regarding the infinitesimal dosage, sneered at by Dr. Cohen, we need only refer to the half century of successful practice of such men as Hering, Jeanes, and others, as sufficient answer. Infinitesimal doses, though strongly urged by Hahnemann in the *Organon*, were not the only doses recommended or used by him. In his article upon "The Cause and Prevention of Asiatic Cholera," he recommends drop doses of a strong solution of camphor given very frequently, "at least every five minutes;" he also suggests that some shall be evaporated near to the patient, that it may be inhaled; and further, recommends that enemata of warm water

containing small quantities of camphor be employed. This certainly is sufficient to show the falsity of the assertion that to be a homœopathist the prescriber must give infinitesimals only.

In reference to the term "spiritual," criticised by Dr. Cohen, let it be remarked that Hahnemann nowhere in the original uses the word; he says, "Geistartig," "dynamisch," *i. e.*, "spirit-like, dynamic." This term is applied to the force, which is invisible. Again, Hahnemann nowhere ridicules the *vis medicatrix naturæ* in the sense placed upon his words by Dr. Cohen. He ridicules the efforts made "to follow unthinking and unreasoning nature," just as Dr. Cohen would ridicule the engineer who would plan a canal in most tortuous lines, because, forsooth, nature thus finds for her rivers outlets to the ocean. Man's reason should discover better ways.

In conclusion, let me urge the medical profession to accept Hahnemann's challenge, "Machts nach aber machts recht nach." Let the experiments be made in the spirit of true investigation, not in a spirit of wanton opposition and bigotry. Let it be a search for the truth. Let homœopathy—*i. e.*, a practice in accordance with the "law of similars," "the single remedy," and the "smallest dose that will cure," three points upon which Hahnemann based his work—stand or fall by the test. Theorizing teaches nothing: education, trained observation, and experiment alone will suffice.

Aug. Korndœrfer.

1728 Green St. Nov 20, 1889.

TOLEDO.

To the Editor of The Medical News,

Sir: A medical centre may be defined to be concentrated medical influence, the lengths of the radii being but the estimates of the strength and worth of the concentration, by those cognizant of its existence.

These medical centres have points of similarity to other concentrations: the electric light, for instance, increases in apparent power as one approaches it. For this reason, perhaps, the medical influence of Toledo is not greatly felt in Chicago or other distant points.

The charitable-mindedness of our neighbors allows us to indulge in the pleasurable belief that our influence goes out to and beyond the towns around us.

A growing, hustling city of 100,000 inhabitants cannot but present points of interest to medical men. Spread over a large area, and generally upon sandy soil, we have two factors in the maintenance of health not possessed by most cities, and our low mortality, scarcely above the lowest, is one of our prides.

A physician who leaves a country practice of $1500 a year and comes here to locate makes a mistake, unless he has reasons other than a desire for a large practice. The exact number of physicians in Toledo is unknown, but, as elsewhere, the profession is overfull.

Some of our best physicians are connected with one or the other of two medical colleges, in which altogether there are about thirty-five students.

The Toledo Medical Association, with about sixty members, meets twice a month, and the meetings are growing in interest, and the quality of work done is good. One medical journal is published monthly.

The Northwestern Medical Association, born in Toledo, and now nineteen years old, meets here this week.

We have several hospitals, one being partially under the control of homœopaths.

Both lay and professional men have been searching for the cause of the unusually large number of cases of diphtheria that have occurred lately in two wards of the city. Dogs and cats have been accused of carrying the disease from one family to another, and faulty sewers and other forms of nastiness of generating the poison. The mortality of cases reported has been twenty-five per cent.

Eye and ear, and throat and nose are the only specialties that seem to be profitable here, and with these exceptions every physician does a general practice, not because we do not like to send our patients to specialists, but because each one feels the need of the work himself.

Several of our physicians were in Europe this summer, and thus, perhaps a little slowly, but surely, are we becoming cosmopolitan.

NEWS ITEMS.

Tests of Electrical Execution Apparatus.—At the New York State prison a bull was recently made the subject of an experiment with the electrical machine designed for the execution of criminals. The animal was instantly killed with a voltage of 900. The speed of the dynamo could not be steadily maintained much above a voltage of 400, in consequence of incomplete machinery. The instruments for measuring the currents were trustworthy, being those that had been furnished for the occasion by the Johns Hopkins University. The apparatus has a capacity of 1500 volts, which is more than will be needed. Dr. A. D. Rockwell, of New York, was present as one of the State commission of experts, and stated that he was convinced that 1000 volts would invariably kill a human being painlessly, and that as a protracted contact is unnecessary, the disfigurement of the body by burning will be avoided. In regard to the electrical resistance of the human body, as compared with that of the bull, the opinion is that it is much less.

A Psychological Museum.—A curious museum has been established at Florence, Italy, by ministerial decree, to be known as the "Psychological Museum." It might be termed the museum of the human passions, if the officially announced programme is carried out. The eminent ethnologist and sanitarian, Dr. Mantegazza, has been charged with the development of the new undertaking. Lectures on experimental psychology will, it is stated, be delivered under the direction of Dr. Mantegazza.

A Definition of Faith-cure.—The Rev. Dr. Lyman Abbott, of Brooklyn, is credited with giving the following definition of "faith-cure" from his standpoint: "When I get sick, I will show my faith in God by securing the best doctor I can find, getting the best human skill, and following the directions given me by a good physician. Faith does not consist in refusing to take medicine, but it is the using of all the means of cure which is given us to use, and medicines have been shown to be one of those means."

The Health of London in 1889.—The *Lancet* of January 4th contains a summary of the mortality in London during the past year, from which the inference is drawn that the health of that city was by far the best that has been known in modern times, or since registration reports have been kept. The total number of deaths was 75,683, a smaller number than in 1870, when the population was a million less than in 1889. The death-rate was 17.5 per 1000, while in 1888 the rate was 18.5 per 1000, a gain of one in the thousand, despite a growing population. This is so remarkable that the *Lancet* questions its reliability, but concludes to accept it as a mark of the sanitary improvement of that great metropolis. The difficulty in the way of getting a confessedly genuine death-rate is seen in the fact that, as there has been no census in London since 1881, the basis of population for the computation of a death-rate must be the estimate of the registration authorities; and the suspicion constantly arises that the estimate has been placed too high, year by year.

Electric Lights in the New York Hospital.—The lighting of the New York Hospital has been changed from gas to electricity. With this change it is thought that the quality of the respirable air in the institution has improved, and that the temperature of the wards is under better control. The plant includes 700 Edison lamps. The operating room is fitted out with these lamps, so that operations may be performed at any hour of the night or day.

Bequest to the Maine General Hospital.—At the death of Mrs. H. H. Hill, of Augusta, Me., the Maine General Hospital will fall heir to $40,000 bequeathed by the late Dr. H. H. Hill.

Suit against an Ophthalmic Surgeon.—Dr. Hermann Knapp, of New York City, is the defendant in a suit for $5000 damages. A death from pneumonia took place at his ophthalmic hospital after an operation for cataract. The allegation of the representatives of the deceased is that the fatal pneumonia might have been obviated by better attendance and care. The rejoinder is that good treatment and care were employed, and that pneumonia may arise in the best of surroundings and in the least expected manner.

Meeting of the Fifth District Branch of the New York State Medical Association.—The next meeting of the Fifth District Branch of the New York State Medical Association will be the sixth annual meeting, to be held in Brooklyn on Tuesday, May 27, 1890. All Fellows desiring to read papers will please notify the secretary, E. H. Squibb, M.D., P. O. Box 94, Brooklyn, N. Y.

A Monument for Washington's Mother.—Largely through the instrumentality of Marion Harland, who is well known by reason of her essays upon housekeeping and the care of infants, a scheme has been set on foot with the object of collecting a sufficient sum to renovate thoroughly and finish the imperfect and partly ruined monument which was begun in 1843 over the grave of Mary, the mother of Washington.

As is well pointed out, Washington's entire training, both moral and physical, depended upon his mother's wisdom, owing to the early death of his father.

The *Home-Maker*, of New York, will receive subscriptions for any amount toward this purpose, and will give to the fund seventy-five cents out of every $2.00 subscription, provided that the subscription is marked, "For Mary Washington Monument."

Intubation in Italy.—The first intubation of the larynx for croup in Italy was recently performed by Dr. Egidi, of Naples, who still holds that tracheotomy is usually the preferable operation.

Hospital Appointments.—Dr. Byron Whitford has recently been made a visiting physician to the Rhode Island Hospital, *vice* Dr. J. W. C. Ely, resigned. Dr. Joseph H. Akers succeeds Dr. Whitford on the staff of out-patient physicians.

Since September, 1889, the affairs and departments of this hopital have been running smoothly and successfully under the administration of its young, but efficient, superintendent, Dr. John M. Peters, whose term of service as interne in the same institution expired but a few months previous to his appointment as superintendent.

Alcohol in Patent Medicines.—In the report on nostrums, proprietary medicines, and new drugs, which was read before the American Association for the Cure of Inebriates, is found in the appendix the following list of the results of the analyses of a large number of well-known patent medicines, which is of interest not only to the physician, but to the student of human nature, in view of the readiness with which charlatanism can hoodwink persons who in other matters are supposed to have the ordinary quantity of common sense:

	Per cent of Alcohol.
Dr. Buckland's Scotch Oats Essence . . . (Also ¼ gr. morphine to the ounce.) A more insidious and dangerous fraud can scarcely be imagined, especially when administered as this is recommended, for the cure of inebriety or the opium habit.	35.
The "Best" Tonic	7.65
Carter's Physical Extract	22.
Hooker's Wigwam Tonic	20.7
Hoofland's German Tonic	29.3
Hop Tonic	7.
Howe's Arabian Tonic. "Not a rum drink" .	13.2
Jackson's Golden Seal Tonic	19.6
Liebig Co.'s Coca Beef Tonic	23.2
Mensman's Peptonized Beef Tonic	16.5
Parker's Tonic . . . . . "A purely vegetable extract. Stimulus to the body without intoxicating. Inebriates struggling to reform will find its tonic and sustaining influence on the nervous system a great help to their efforts."	41 6
Schenck's Seaweed Tonic . . . . . "Distilled from seaweed after the same manner as Jamaica spirits is from sugar-cane. It is therefore entirely harmless, and free from the injurious properties of corn and rye whiskey."	19.5
Atwood's Quinine Tonic Bitters	29.2
L. F. Atwood's Jaundice Bitters	22.3
Moses Atwood's Jaundice Bitters	17.1
H. Baxter's Mandrake Bitters	16.5
Boker's Stomach Bitters	42.6

	Per cent. of Alcohol.
Brown's Iron Bitters	19.7
"Perfectly harmless. Not a substitute for whiskey."	
Burdock Blood Bitters	25.2
Carter's Scotch Bitters	17.6
Colton's Bitters	27.1
Copp's White Mountain Bitters	6.
"Not an alcoholic beverage."	
Drake's Plantation Bitters	33.2
Flint's Quaker Bitters	21.4
Goodhue's Bitters	16.1
Hartshorn's Bitters	22.2
Hoofland's German Bitters	25.6
"Entirely vegetable and free from alcoholic stimulant."	
Hop Bitters	12.
Hostetter's Stomach Bitters	44.3
Kaufmann's Sulphur Bitters	20.5
"Contains no alcohol." (In fact, it contains no sulphur, but 20.5 per cent. alcohol.)	
Kingsley's Iron Tonic	14.9
Langley's Bitters	18.1
Liverpool's Mexican Tonic Bitters	22.4
Pierce's Indian Restorative Bitters	6.1
Z. Porter's Stomach Bitters	27.9
Rush's Bitters	35.
Dr. Richardson's Concentrated Sherry Wine Bitters	47.5
"Three times daily or when there is sensation of weakness or uneasiness at the stomach."	
Secor's Cinchona Bitters	13.1
Shony's German Bitters	21.5
Job Sweet's Strengthening Bitters	29.
Thurston's Old Continental Bitters	11.4
Walker's Vinegar Bitters	6.1
"Free from all alcoholic stimulants. Contains no spirit."	
Warner's Safe Tonic Bitters	35.7
Warren's Bilious Bitters	21.5
Wheeler's Tonic Sherry Wine Bitters	18.8
Wheat Bitters	13 6
Faith Whitcomb's Nerve Bitters	20.3
Dr. Williams's Vegetable Jaundice Bitters	18.5

Impurities of Creolin.—WEYL, of Berlin, has recently made comparative studies of Pearson's and of Artmann's creolin. Creolin furnished by the latter manufacturer was free from nitro-benzol and carbolic acid, but contained naphthalin. In Pearson's creolin, carbolic acid was always present.—*Deutsche medicinische Wochenschrift*, February 6, 1890.

The Use of Resorcin in Whooping-Cough.—The most recent advocate of the treatment of pertussis by resorcin is DR. JOHN W. FARLOW, of Boston (*Boston Medical and Surgical Journal*, February 27, 1890), who reports two well-marked and severe cases in which a spray of resorcin gave prompt relief. In neither case was the usual treatment of benefit. At about the end of the second week of the disease, Dr. Farlow ordered a nasal and laryngeal spray of a two per cent. resorcin solution every two hours. Relief was almost immediate; sleep, which had hitherto been broken by paroxysms of coughing, became undisturbed, and by the fourth day the cough had disappeared, and the children were perfectly well. The atomizations were continued for a few days as a precaution, but there was no return of the cough. Two other children in the author's practice were also cured in a week by the same treatment.

Obituary.—DR. OTTO BECKER, Privy Councillor and Professor of Ophthalmology in the University of Heidelberg, died in that city on February 7th in his sixty-second year. For some years an assistant of von Arlt, in Vienna, he was called to succeed Knapp in the chair at Heidelberg in 1868, and, taking up the work so well begun there, he carried it splendidly forward. Thanks to him, the Heidelberg Eye Clinic has kept its place as a model institution for the treatment and the study of eye disease; and the report of his twenty years' work there, which he laid before the International Congress in 1888, accords with his numerous other publications in showing that ophthalmology has lost one of its strongest and ablest workers in his death.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 25 TO MARCH 3, 1890.

By direction of the Secretary of War, a Board of Medical Officers, to consist of CHARLES SMART, *Major and Surgeon;* VALERY HAVARD, *Captain and Assistant Surgeon;* LOUIS BRECHEMIN, *Captain and Assistant Surgeon*, is appointed to meet at Fort Leavenworth, Kansas, on March 15, 1890, or as soon thereafter as practicable, for the purpose of preparing a manual of drill and instruction for the members of the Hospital Corps, and to examine the equipment of the Corps with a view to its improvement. —Par. 9, *S. O. 47, A. G. O., Washington, D. C.*, February 26, 1890.

LORING, LEONARD Y., *Major and Surgeon.*—Having been found incapacitated from active service by an Army Retiring Board, the extension of leave of absence on surgeon's certificate of disability, granted him in S. O. 34, February 10, 1890, from this office, is, by direction of the Secretary of War, still further extended until further orders, on account of disability.—Par. 3, *S. O. 47, A. G. O., Washington*, February 25, 1890.

SMITH, JOSEPH R., *Lieutenant-Colonel and Surgeon.*—Promoted to be Surgeon with rank of Colonel, February 9, 1890.

BACHE, DALLAS, *Major and Surgeon.*—Promoted to be Surgeon with rank of Lieutenant-Colonel, February 9, 1890.

HARVEY, PHILIP F., *Captain and Assistant Surgeon.*—Promoted to be Surgeon with rank of Major, February 9, 1890.

PATZKE, J. H., *Major and Surgeon.*—The leave of absence for seven days, granted in Orders No. 25, Fort Huachuca, Arizona Territory, February 12, 1890, to take effect the 14th instant, is extended twenty-three days.—Par. 1, *S. O. 18, Department of Arizona*, February 17, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING MARCH 1, 1890.

RUSH, C. W., *Passed Assistant Surgeon.*—Ordered to the Navy Yard, New York.

AUZAL, E. W., *Passed Assistant Surgeon.*—Ordered to the U. S. S "Galena."

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

CHRONIC RHEUMATIC SORE THROAT.[1]

BY E. FLETCHER INGALS, A.M., M.D.,

PROFESSOR OF DISEASES OF THE THROAT AND CHEST, WOMAN'S MEDICAL COLLEGE, AND PROFESSOR OF LARYNGOLOGY IN RUSH MEDICAL COLLEGE, CHICAGO, ILLINOIS.

Synonym.—Chronic rheumatic laryngitis.

Definition.—This is a painful affection of the throat, chronic in character but varying much from time to time in severity, and attended by only slight physical changes in the parts involved. It usually affects the larynx, and, therefore, it has been described as rheumatic laryngitis; still, in many cases it involves the fauces, the hyoid bone, and, possibly, the trachea, and it sometimes does this without involving the larynx at all; therefore, the term chronic rheumatic sore throat is preferable. It is comparatively frequent, and has doubtless existed from time immemorial, but I have been unable to find any description of it prior to that which I gave at the Ninth International Medical Congress, held in Washington in 1887. The affection occurs mainly during the spring and fall of the year, but we also observe it during the winter, and there are occasional cases in which it continues through the summer months. It is more frequent in men than in women. All the cases that I have seen have been in adults from twenty to sixty years of age. It occurs among all classes with the same impartiality as rheumatism of other tissues.

Anatomical and Pathological Characteristics.—There are no anatomical characteristics, but usually there is slight congestion, circumscribed in character but variable.

Etiology.—It is due to the same causes as muscular or articular rheumatism.

Symptomatology.—It comes on insidiously in many cases, but in others suddenly; usually, however, the patient will have been complaining for months before he applies to the laryngologist for relief. Most of the patients who have come to me have previously consulted several physicians and have received almost as many different diagnoses, but all have feared either tuberculosis, syphilis or cancer, many of them having a fixed dread that they are suffering from cancer. The general health is not impaired. The patient complains simply of a localized pain, which is frequently referred to the cornu of the hyoid bone, and I have observed it more often on the right than on the left side. Next in frequency it is felt in the larynx, generally upon one side only. It may be felt, however, in the trachea, the tonsils, and sometimes in the side of the base of the tongue This pain is increased by pressure in nearly all cases, perhaps in all, and it may be increased by phonation or deglutition, but it often completely disappears while the patient is eating. In any case it is liable to shift its position from time to time, though frequently it is persistent for a long period in one locality. Sometimes, instead of an actual pain the person will complain simply of a sensation of fulness or swelling of the part, or a feeling of dryness, itching or burning; or it may simply be a sensation of discomfort which he cannot well describe. Usually the voice is not affected, but it is common for these patients to complain of fatigue after using it a short time. We find no constitutional symptoms, no fever, and the pulse is not quickened excepting from alarm. Usually there is no cough, but in some cases, especially where the larynx is involved, a hacking and annoying cough is a symptom. The digestive organs may act perfectly, but ordinarily we find the tongue more or less covered with a white or yellowish-white coating, and although the appetite is usually good the patient is often troubled with eructations of gas from the stomach, and with flatus. The bowels are apt to be constipated. Upon laryngoscopic examination we may find localized congestion confined generally to a small spot in the region of the pain, and there is sometimes slight swelling. We find, however, that the congestion diminishes or disappears, or changes to other localities from time to time, therefore there is nothing characteristic in the appearance of the parts.

Diagnosis.—The affection is liable to be mistaken for neuralgia, for enlarged glands at the base of the tongue, for enlarged veins, for chronic follicular tonsillitis or glossitis, for syphilitic or tubercular sore throat, for tobacco sore throat, or for cancer. The essential points in the diagnosis are the uncomfortable sensations of pain, which change usually with the changes in the weather, a rheumatic diathesis, and the absence of any distinct physical signs.

From varicose veins, enlarged glands at the base of the tongue, and from follicular tonsillitis or glossitis,

[1] Read before the Chicago Medical Society, February 17, 1890.

all of which sometimes present similar symptoms, this disease is to be diagnosed by a careful inspection of the part, by the course of the disease, and by the results of treatment. By inspection we may at once ascertain whether the veins or the glands at the base of the tongue are enlarged; but, unfortunately, we cannot tell whether enlargement of the glands or a varicose condition of the veins is the cause of the patient's symptoms. Some patients have these conditions and yet suffer no inconvenience whatever, while in others they give rise to serious discomfort. Therefore, if we find varicose veins or enlarged glands at the base of the tongue, with evidence of what seems rheumatic pain in this locality, we will have to remove these conditions before we can exclude them as the cause of the patient's discomfort. If the patient has a rheumatic diathesis, which can be ascertained by inquiry, it is a point in favor of the diagnosis of rheumatic sore throat.

In follicular tonsillitis and glossitis the signs, upon inspection, are characteristic, and we may usually take it for granted that the symptoms of which the patient complains come from these diseases. We might possibly be mistaken in cases of this sort, but the results of treatment would clear up the diagnosis. Sometimes the diagnosis is extremely difficult, but in the majority of cases, having inquired carefully into the history and excluded the affections I have spoken of, we may make an accurate diagnosis.

From syphilis this affection may be distinguished by the history and physical signs. In the early stage of syphilis and in the secondary and tertiary attacks of the disease there are in nearly every case physical signs which are characteristic, which signs never occur in the disease under consideration. There are occasional instances of syphilitic sore throat where the signs are not characteristic, but in these I have never known the patient to complain of the persistent pain or discomfort which characterizes the rheumatic affection, and I have seen no reason for confounding the two diseases.

From tuberculosis we may distinguish this by the absence of the constitutional symptoms in the rheumatic affection and their great prominence in the tubercular disease; the moderate pain or discomfort in the rheumatic affection and the severe pain in the tubercular disease; by the absence of ulceration in the former, while in the latter we find superficial ulcerations, which in many cases extend over a considerable part of the region in which the patient complains of pain, while in occasional instances there is deep ulceration.

From tobacco sore throat it may be distinguished by the history, and by the absence of plaques that appear as if the surface had been brushed over with nitrate of silver. However, there are cases of tobacco sore throat in which we find no physical signs, but in these the patient usually complains of a burning sensation in the part that is relieved soon after the tobacco is discontinued. If we find that the patient is an habitual user of tobacco, and stopping its use improves his symptoms at once, and if there are no symptoms of rheumatism in other parts of the body, there will be no difficulty about the diagnosis.

From neuralgia it is often difficult to distinguish the rheumatic sore throat. The presence of slight congestion or swelling is of considerable value in the diagnosis, for in neuralgia there are not likely to be any of these local signs. In most cases of rheumatic sore throat pressure increases the pain, while in neuralgia it does not increase it, but may relieve it. In rheumatic sore throat changes of the weather from fair or clear to cloudy and damp almost always aggravate the symptoms, while in neuralgia they have but little effect. In neuralgia of the throat it is common for the patients to complain of pain in the latter part of the day when they begin to get tired, or after any exertion which makes them fatigued. In rheumatic sore throat the pain may be worse in the morning, and is not particularly increased by fatigue.

From cancer we distinguish it by the physical signs. In all cases of cancer which I have met there have been early and distinct physical changes, with more or less induration, gradually increasing irregular swelling, and finally deep ulceration. These changes do not occur in rheumatic sore throat. In cancer of the throat the patients are not likely to experience pain long before some of these physical alterations occur. In the rheumatic trouble pain is the essential symptom, and the physical changes are not marked.

Prognosis.—Unless relieved by treatment we may expect these cases to continue for several months, or even years, but there is no danger so far as life is concerned.

Treatment.—In treating these cases our first attention should be directed to prophylaxis. With this in view we must be careful that the patient is well clothed and housed, and that he is not exposed to undue changes of temperature or to wet or damp atmosphere. Rheumatic patients should always wear either wool or silk next to the body throughout the whole year, light in summer and heavy in winter, and it should be worn both night and day. They should be careful that all the excretory organs of the body perform their functions properly. They should eat sparingly of such albuminous substances as meat or eggs, and should live largely on vegetables or fruit. The vegetable acids are often advantageous. Whatever is eaten it is especially important that digestion be perfectly performed so that the system be not poisoned by the formation of ptomaines.

For the local treatment of the disease sedative or stimulant applications may be made with almost equal chances of relief. Applications of the tincture of aconite to the painful spot four or five times a day will sometimes give considerable relief. I have frequently found relief from the application of stimulants, as, for example, solutions of sulphate of zinc. The application of morphine in solution or in powder is sometimes a source of much comfort to the patient. I have derived more benefit, I think, from the application of a spray composed of morphine, carbolic acid and tannic acid, in glycerin and water, than from anything else. This solution consists of 4 grains of morphine, 30 grains each of carbolic and tannic acids, and 4 drachms each of glycerin and water. I apply it in full strength, and frequently give it to the patient in a solution of half this strength, to be used daily in the form of spray. In some cases the strong tincture of iodine gives relief; in others the application of a 60 grain solution of nitrate of silver has proved beneficial. These applications do good on the same principle that blisters sometimes relieve a rheumatic joint. The most important part of the treatment is the internal medication. For this purpose salol, the salicylate of sodium, iodide of potassium, guaiac, phytolacca, and the oil of gaultheria may, one or all, be used at different times with benefit. The salicylate of sodium in doses of 7½ to 10 grains four or five time a day; the oil of gaultheria in doses of 15 minims three or four times a day; the ammoniated tincture of guaiac in doses of a teaspoonful three or four times a day, or the resin of guaiac in lozenges, frequently repeated, are of considerable value. But I have derived the most benefit from the extract of phytolacca and salol, combined with a laxative, and sometimes with the iodide of potassium, or with the bromide of potassium for its sedative effects. I give the extract of phytolacca in doses of from 2 to 4 grains, and salol in the same dose, or sometimes in doses of 10 grains. Tincture of bryonia and of cimicifuga have been claimed to be valuable remedies in the treatment of rheumatism. I have used them both, apparently with slight benefit in some instances, but the obstinate cases have done better under the phytolacca and salol, with the occasional use of the other remedies already suggested.

I have records of over fifty well-marked cases of this disease observed during the past four or five years, from which I deduced what I have said in this paper regarding the symptomatology, prognosis, and treatment.

70 STATE STREET.

The Astor Bequests to Charities.—By the will of the late John Jacob Astor two hospitals in New York City are benefited to the extent of $100,000 each; namely, the St. Luke's Society and the new Cancer Hospital.

DRAINAGE IN ABDOMINAL AND PELVIC SURGERY.[1]

BY JOSEPH PRICE, M.D.,
OF PHILADELPHIA.

THE absolute necessity of drainage in abdominal surgery has led to a careful estimate of its value in all surgery. Wherever there is serous effusion or leakage of any kind in the line of incision or in the cavity caused by the removal of any neoplasm, the cicatrization of the wound is interfered with, either by the nature of the fluid, or by the mechanical pressure exerted by that fluid under tension. In the pelvis the presence of fluid as a pathological accumulation at the seat of removal, involves a nidus of remaining unhealthy tissue, where physiological or healthy digestion is impossible. Illustrative of this fact I have the following specimens: In the first there is a pyosalpinx with an appendicitis and cœcal ulcer. The cœcal ulcer necessitated the stitching of the bowel, while the appendix stump was inverted and closed peritoneally. The pus-tube was universally adherent, and in its enucleation débris of unhealthy tissue was necessarily left to a greater or less extent. The value of drainage is here apparent. In the second case, the condition was analogous, save that there were present double pus tubes with an ovarian abscess.

The third specimen is that of an extra-uterine pregnancy, with rupture, recurring hæmorrhages, and general peritonitis. The abdomen was full of blood. In a fourth specimen there is a small adherent cyst, with a pus tube on the opposite side.

This group of cases was operated on in the last ten days, and all the patients were suffering from extreme exhaustion, from loss of blood, and the presence of pus. In all these cases the trouble is universally of long standing, where all imaginable complications existed. Foremost among these complications were the bowel adhesions. In one week I was compelled to stitch the intestine five times. In this connection the care required in dealing with diseased serous surfaces claims especial attention. Not only must the primary lesion of the intestine be intelligently dealt with, but the secondary disease incident to its pathological adhesions, and the ragged remains incident to its separation must also receive extreme attention. In no way can they be rendered inoffensive, save by drainage. In speaking of remaining débris, it may be well to insist upon a distinction between a remainder that is absolutely unavoidable, and that which occurs through timidity, inexperience, ar gross carelessness. Such remainders as these are nothing less than criminal. When I find them or hear of them, I know one of two or three things has caused them. When I hear of a

[1] Read before the Philadelphia County Medical Society, February 2, 1890.

patient being operated upon by the same man two or three times, I estimate the operator's ability or conscience accordingly. All the antiseptics, whether in bottles or consciences, will not make careless surgery give good results, or free the patient from the dangers of repeated operations. In four cases which have lately come under my notice, three of the patients died of operations repeated not less than three times. Flesh and blood will stand about this much. If the tension is too great, the harp-string will strain and snap, be it saint or sinner that plays on it. Necessary remainders are those produced by adhesions, in parts not removable, save at a risk greater than is involved by leaving them. Such remainders as these should be trimmed to the utmost. If they are on the bowel, and their presence threatens too much the welfare of the patient, intestinal anastomosis or bowel resection may be resorted to.

Mechanical treatment of all bleeding points need not here be discussed. After all major leakage has been controlled, the hot drenching of the abdominal or pelvic cavity must be resorted to, for the removal of débris, shreds, and clots. After this, even sponge or lint packing may be found necessary. The insertion of the drainage tube down to the lowest involved locality must then be made. Care must be taken that the tube makes no injurious pressure upon either the diseased or healthy portion of the intestine. In either case it will be fatal to uninterrupted recovery, and is likely to produce fistula. The use of large drainage tubes either in abdominal or general surgery is to be deprecated as unnecessarily impeding healing and encouraging suppuration. A small tube, with a calibre sufficient to insure its not being obstructed by escaping fluids, when somewhat viscid, is all that is called for.

The failure of the earlier operators to appreciate the cause of death in their more complex cases, was, at the bottom, really the cause of that critical period of ovariotomy when the congestive chills of dread made surgeons tremble and hesitate at deciding for or against the operation. In the earlier post-mortems of patients operated upon, the pelvis was found full of serum and clots. Had the fear of this abdominal sanctuary not been by tradition so dreadful, that it was thought more rash to open it to a drainage tube than to close it to gallons of fluid and pounds of clot, the tale would have been different and cavilers sooner silenced.

Purulent cases, where a nidus of infection could not by any means be primarily removed, would have yielded to drainage, while they died of turpentine and poultices, that made the abdomen warm, to hasten the infection. The same is true of all inflammatory products arising from any source whatever. This is a point well illustrated by two cases of puerperal peritonitis I lately operated upon. They had puerperal fever of five weeks' standing, with high temperature and general collapse, and were full of pus to the umbilicus. There were huge ovarian abscesses, with bowel adhesions. The tubes and ovaries were removed and the bowel carefully stitched. The abdominal cavities were flooded with hot water twice, which did more to bring up the pulse than anything else. The result is typical — complete recovery without bad symptoms.

It must be insisted upon that the mortality of this work would be so great without drainage that the cases would have to be left to their fate by the surgeon in simple self-defence. Operators who will not recognize this as proven beyond doubt, will still go on having mortalities that they cannot explain. Their cases, while not worse than others, will suffer by comparison, and their bad results be apologized for.

While operation in all these cases is to be insisted upon, we will constantly see others where typical surgery is impossible; the patients are too far gone to allow prolonged operation. In such cases the immediate cause of the dangerous condition, if pus, is to be eliminated by drenching and drainage, and after the patient has rallied, some days later, the operation may be completed. Too much surgery in extremely debilitated patients will kill just as surely as none at all, as I have long since insisted upon and practised with gratifying results.

OPERATIVE METHODS AS ILLUSTRATED BY THE HISTORY OF OVARIOTOMY IN AMERICA.[1]

By LEWIS S. McMURTRY, M.D.,
of Louisville, Ky.

The history of ovariotomy is the history of abdominal surgery. For many years after the establishment of this operation abdominal surgery was limited to the removal of ovarian tumors. The knowledge and experience gained thereby led to other procedures, until the present proud position of peritoneal surgery was attained. Beginning in America in 1809, it has been persistently and zealously cultivated by American surgeons up to the present time. A retrospect of the origin, early history, struggles, and triumphs of this heroic branch of surgery is replete with instruction. That its pioneers were subjected to criticism and abuse, leading oft-times to professional ostracism; that they were treated with incredulity, and charged with legalized murder; and throughout all this misrepresentation and persecution that they pursued the stern line of duty, are circumstances which make this the most thrilling chapter in the history of American surgery.

[1] Read, by invitation, before the Philadelphia County Medical Society February 25, 1890.

It is the purpose of this paper to deal with methods rather than men, and to endeavor to deduce from the record some lessons bearing upon the practice of the present time.

In December, 1809, Dr. Ephraim McDowell, at his home in Danville, Kentucky, performed the first ovariotomy. The writer of this sketch was born and reared near this town, educated there, and resided there until recently. Having known since my boyhood the immediate family and former patients of Dr. McDowell, I have had exceptional opportunities to inform myself as to the operator and his work. In 1793 and 1794 McDowell was a student of medicine in Edinburgh, where he was a pupil of John Bell. From this eminent teacher he learned the nature of ovarian tumors, and was informed of the perils which would be attached to any attempt at their removal. He knew that no surgeon, however great his skill, had ever attempted such a bold and perilous procedure. Fifteen years after his return to America, and after attaining wide-spread celebrity as a surgeon, especially as a lithotomist, he performed his first ovariotomy. The operation, of course, was executed without an anæsthetic. The incision was made to the left of the median line, about three inches external to the border of the rectus muscle, and was nine inches in length. After opening the peritoneum he first tied the pedicle with a strong ligature, and then cut open the tumor and removed its contents. He then divided the pedicle and removed the sac. As soon as the incision was made into the abdomen, he states, the intestines rushed out upon the table, and were not replaced until the operation was completed, which, he adds, occupied twenty-five minutes. He then turned the patient upon the left side to allow all fluids to escape. He closed the incision with interrupted sutures, and brought out the ligature attached to the pedicle at the lower angle of the wound. Adhesive strips and a bandage completed the dressing; the patient was put to bed, and he prescribed "a strict observance of the antiphlogistic regimen." At the end of twenty-five days the patient returned home in good health.

The special features of McDowell's technique worthy of note are: (1) The incision was made through the muscular layers of the abdominal wall three inches external to the rectus muscle. (2) The cyst was not evacuated until after the pedicle was lighted. (3) An effort was made to cleanse the peritoneum of fluids. (4) Drainage was sought by bringing the ligatures out at the lower angle of the wound. (5) The operation occupied only twenty-five minutes, expedition being more hastened, doubtless, by the absence of an anæsthetic than otherwise.

McDowell operated thirteen times, with the result of eight recoveries and five deaths. In his report of his second case he uses the expression: "I laid her side open," as in the former case. In his third case he adopted the median incision, saying in his report of this case: "I changed my place of opening to the linea alba."

Dr. McDowell was a man of splendid presence and aristocratic bearing. He was quite a "dressy" man, neat in his appearance and cleanly in his person and habits. That McDowell appreciated the responsibility he had incurred, and was aware that he was establishing a great operation, destined to add lustre to the science and art of surgery, is apparent in the following extract from his reply to a Dr. Henderson, who had criticised McDowell's report for its want of "particular detail." Replying through the columns of the *Eclectic Repertory and Analytical Review*, of Philadelphia, McDowell says:

> "I thought my statement sufficiently explicit to warrant any surgeon's performing the operation when necessary, without hazarding the odium of making an experiment, and I think my description of the mode of operating, and of the anatomy of the parts concerned, clear enough to enable any good anatomist, possessing the judgment requisite for a surgeon, to operate with safety. I hope no operator of any other description may ever attempt it. It is my most ardent wish that this operation may remain to the mechanical surgeon forever incomprehensible."

This quotation stamps McDowell as a surgeon of broad and elevated views, fully aware that he had opened a new and rich domain in surgery.

McDowell first operated in 1809, and in July, 1821, Dr. Nathan Smith, Professor of Surgery in Yale College, performed ovariotomy at Norwich, Connecticut. Dr. Smith had never heard of McDowell's work, and operated in an entirely original way. The incision was made in the median line, and was three inches in length. He states that he waited until the blood ceased flowing before he opened the peritoneum. The omentum being adherent, he tied it away with ligatures made from a kid glove. The pedicle was also tied with the same material, the ligatures cut short, the pedicle dropped, and the incision closed. The patient made an uninterrupted recovery, and sat up and walked at the end of three weeks. Dr. Smith undertook another operation for ovarian tumor, but desisted on account of adhesions, and closed the incision. The patient recovered from the operation. Notable features of his technique were: (1) the short incision; (2) protection of the peritoneum from the blood of the incision; (3) ligature of omental adhesions; (4) ligature of pedicle, ligature cut short, and pedicle dropped; (5) animal ligatures.

Dr. Alban G. Smith, of Danville, Ky., was the third to perform ovariotomy. He assisted McDowell in several of his operations, and operated on May 23, 1823. He reported the operation in the *North*

American Medical and Surgical Journal, January, 1826. He followed McDowell's method in operating, and brought the ligature out through the lower angle of the wound. His patient recovered. That surgical opinion and practice often travel in a circle is aptly illustrated by the fact that he administered a decoction of senna to the patient the night after the operation, producing free evacuations the next day, and several the day after. Peaslee mentions this to illustrate the crude methods of early days. We all know now that such medication is based on sound principles, and Dr. Alban G. Smith would, if living, find himself thoroughly *en rapport* with the most advanced methods of the day.

McDowell died in 1830. Nathan Smith did not press his work further after his second operation, which was only an exploratory incision. From this period until 1843 the operation lapsed into obscurity, and was practically abandoned by the profession. A few brave surgeons would occasionally attempt it only to abandon their purpose when adhesions were encountered. Among these were Trowbridge, of New York; Mussey, of Dartmouth; and a few others. In 1829, Rogers, of New York, operated successfully, adopting the method of treating the pedicle which Nathan Smith had practised. Billinger, of Charleston, S. C., operated successfully in 1835, tying the pedicle with animal ligatures, cut short, and pedicle dropped, after Nathan Smith's method. From 1835 until 1843 there were absolutely no cases of ovariotomy in this country. In the latter year, Dr. John L. Atlee, of Lancaster, Pa., and Dr. Alexander Dunlap, of Springfield, Ohio, began their work, joined by Dr. Washington L. Atlee, of Philadelphia, the following year, and revived the operation in America.

In England, Charles Clay did his first operation in 1842. Mr. Spencer Wells began to operate in 1858. The status of the operation in Great Britain at the time the Atlees and Dunlap began their work may be inferred from the fact that the first successful ovariotomy in a London hospital occurred in 1846, Mr. Cæsar Hawkins being the operator, three years after the revival of the operation by the Atlees and Dunlap. J. Taylor Bradford, of Kentucky, entered upon his series of thirty operations, with twenty-seven recoveries, in 1853; and Gilman Kimball, of Lowell, Mass., joined his colleagues in the great work in 1855. Peaslee states that the operation did not secure a permanent footing in the United States until 1855, and then only in the country. The surgeons of the cities, as a rule, opposed it for some years afterward. Ten years later, 1865, the operation was generally accepted. Operative surgery received a great impetus in the discovery of anæsthesia.

No one can read Dr. John L. Atlee's report of his first case, which was the first double ovariotomy ever performed, without recognizing the courage, skill, and sagacity of a master in surgery. He operated with rapidity; he carefully arrested all bleeding; he cleansed the peritoneum, and used silk ligatures. He transfixed the pedicle with a double silk ligature, and tied each half with half the ligature. He adopted McDowell's method, and brought the ligatures out through the lower extremity of the wound to secure drainage. Dr. Washington L. Atlee performed his first operation in March, 1844. It was unsuccessful. His next was done five years later, and was successful. He adopted the methods of his brother in operating. Dunlap treated the pedicle after McDowell's method. Dr. E. R. Peaslee began his series of ovariotomies in 1850, and Sims, Thomas, and Emmet, a few years afterward, joined in the work. In October, 1871, Peaslee had collected 739 ovariotomies performed in this country, with successful results amounting to about sixty-eight per cent.

In 1858 Mr. Jonathan Hutchinson, of London, performed two ovariotomies, and devised the clamp for fixing the pedicle externally. This method was adopted and modified by W. L. Atlee, who led all American operators of his day in the number of his cases. The clamp came into general use, and had the confidence of ovariotomists generally until a recent period. For many years the method of securing the pedicle was considered the pivotal point in the operative technique, and the ingenuity of operators was expended on this feature of the opetion. Under the leadership of Spencer Wells in England and Atlee in the United States, the clamp superseded other methods.

The causes of death after ovariotomy were enumerated at this same period (1873), by Peaslee, as follows, his deductions being based upon post-mortem examination of fifty cases. The causes are given in the order of frequency: Peritonitis, septicæmia, shock, exhaustion, hæmorrhage, strangulation of intestine, diarrhœa, erysipelas, tetanus, and ulceration through the bladder. Based upon this view of the pathology, peritonitis was regarded as the greatest danger to which a patient was subjected after ovariotomy, and opium in heroic and repeated doses, in accordance with the accepted therapeutics of that day, was the conspicuous feature of the after-treatment. This treatment was universally accepted by the profession. The turning-point in the history of ovariotomy in America dates from the correction of this error in pathology. When it became known that the greatest peril of a patient during and after ovariotomy is septicæmia; and that the peritonitis hitherto attributed to traumatism was in reality due to septic infection, this department of surgery entered upon an advance which in grandeur and brilliancy has no

parallel in the history of our art. This great fact was heralded in America by Marion Sims and met with universal acceptation. Sims instituted a method of drainage after ovariotomy by puncturing Douglas's cul-de-sac and passing a tube into the vagina. This was soon abandoned, though it is now practised by Martin, of Berlin.

With the acceptance of the fact that the supreme danger after ovariotomy is in septic infection, a new era in ovariotomy began in America. Synchronous with the adoption of operative methods and after-treatment based upon this knowledge the clamp was abandoned, and the intra-peritoneal treatment of the pedicle was restored. The most important single contribution made to pelvic and abdominal surgery is the system of surgical cleanliness instituted by Lister. Burdened with the spray, pads, macintosh, and chemical solutions at first, it has been simplified and stripped of its dangers and its burdens, and found to consist, in its essence, of absolute cleanliness. With the application of this principle—the outgrowth in practical surgery of the researches of Pasteur, Lister, Koch, Watson-Cheyne, and others upon the nature of fermentation, putrefaction, suppuration, and septic infection—results have been obtained of which our predecessors scarcely dreamed. From ovariotomy the work extended to other organs within the peritoneal envelope, until all have been included.

When Marion Sims, a few years ago, confidently predicted that the time was near at hand when gunshot wounds of the abdomen would be treated by abdominal section and suture of the wounded viscera, it was considered by many as the dream of an erratic man of genius. Already a number of successful cases have been recorded in America. Ovariotomy has within a few years grown from an operation with desperate mortality to be the most successful major operation in surgery. From a last resort, attempted by only a few bold spirits in the profession, it is now done habitually by surgeons in every State of the Union. Along with the extension of surgical treatment to the other organs invested by the peritoneum has come a greater perfection in operating, so that the work of the best operators has a perfection and finish approaching the ideal in surgical art.

Time will not permit even an enumeration of the additions contributed in America to modern ovariotomy and the valuable contributions to the surgery of the intestines and other abdominal organs, all of which is the out-growth of the work inaugurated by McDowell.

In conclusion I will venture to direct attention to one important lesson to be deduced from the study of the history of ovariotomy in the country of its birth. We have seen from what has preceded that the operation grew to its grand proportions in the hands of a few. All who have labored in this field of surgery realize how difficult is diagnosis even with experience; how exacting the technique; how varied the work in cases apparently similar; and how fatal an error. Of all departments of surgical practice none requires such rigid and prolonged apprenticeship for successful results. No surgeon can rely upon simple cases. What is most needed to maintain the high standard fixed for abdominal surgery by its founders and its eminent practitioners is men in every community especially trained and equipped for this special work.

SULPHONAL IN CHOREA.

By JOHN A. JEFFRIES, M.D.,
of Boston.

The treatment of chorea has proved to be such a stumbling-block in the way of physicians that it is only with reluctance that the writer has ventured to bring the use of sulphonal in such cases into notice. It may be that my results are purely accidental; that they are purely imaginary on my part does not seem possible, as the results have, in several cases, been determined by other physicians, and have satisfied the patients.

Sulphonal has recently been advised in various forms of muscular spasm, but not, so far as I know, in chorea; yet, judging from my experience, the drug is able, at times, to suppress promptly the choreic motions.

The cases reported are taken from my service at the Boston City Dispensary, with the exception of two treated by me in the service of Dr. Knapp, at the Hospital. A good many others have been treated with about the same results, but time and expense have prevented any large series of cases.

It will be seen that only five of the cases were simple chorea—that is, first attacks of recent origin. These all recovered within three weeks. In two arsenic had failed, in two was never used; in the fifth either arsenic or sulphonal alone failed, but together they were quickly followed by improvement. The other five cases were either of long standing, or second or third attacks; four were at the period of puberty; three of these cases got well at least for a month; in three arsenic had failed, in two was not used. Two have not recovered with any treatment.

To me it seems clear that the sulphonal acted favorably, and that improvement was not simply due to change in the disease, or to arsenic previously given. Nevertheless, I hold that sulphonal is only indicated as an adjuvant to arsenic. On sulphonal alone the patients were apt to grow pale, and clearly showed the need of a tonic. This want arsenic supplies, and, at the same time, directly affects many

cases of chorea. How sulphonal acts I do not know; it was given in the first case to counteract the psychical symptoms, and with a hope of affecting the motions.

CASE I.—Well grown, thirteen-year-old girl, with nothing of note aside from the chorea, but loss of one eye from "the use of eye drops." Claims to have been frightened five years ago, since when has had chorea; much worse in the summer than during the winter. No history of painful or swollen joints. Face, tongue, eye, vocal cords, body, arms, and legs all markedly affected. Motions sharp, extensive and continuous. Has lately suddenly passed water twice. Knee-jerk, heart and lungs normal; bowels regular, vision, o. d. $\frac{5}{IV}$. Mind distinctly affected. Fowler's solution prescribed, July 28, 1888.

August 18. Much improved as to chorea, but has an extensive arsenic eruption on face and body. Stopped Fowler's solution and gave sulphonal, 2 grains three times daily.

25th. Marked improvement, mother thinks that the "second medicine is the best." Dose increased to 5 grains.

Sept. 6. No choreic motion since August 27th. Stopped sulphonal.

15th. Chorea has just re-appeared, as a trace, in tongue and fingers. Vertigo. Sulphonal, 5 grains night and morning.

18th. Possible trace of chorea in fingers.

27th. Well as regards chorea, but slightly anæmic. As this case was found to be amply able to pay it was discharged, and no further record can be given.

CASE II.—Boy ten years old. (August 27, 1888.) Has had chorea each of the last two summers. The first attack was attributed to fright. No history of pain or swelling in joints. Heart normal. Boy very cross and excitable, face and right arm distinctly affected.

Sept. 17. Has used no medicine. Much worse. Speech affected. Ordered Fowler's solution, 5 minims three times daily.

20th. No better; eyelids swollen and stomach irritable. Stopped arsenic and gave sulphonal, 2 grains, morning and noon.

24th. Has improved in every respect; "trembles the least bit."

29th. Worse again; stopped sulphonal. In the course of a month patient ceased to attend. Still had slight chorea.

Here sulphonal certainly appeared to do good at first, but was not continued long enough. The boy belonged to the dirty, shiftless class.

CASE III.—Girl, nine years old. (May 1, 1889.) Three weeks ago had some slight febrile symptoms, pain in the knees, and chorea began at same time. Now has pronounced chorea of all the voluntary muscles, with night attacks. Heart normal. Gave Fowler's solution, 3 minims three times daily.

May 6. No better; changed to sulphonal, 2 grains, three times daily.

8th. Much better; can talk; arms steady, feet nearly so; feels sleepy.

15th. Well, though constipated. Stopped sulphonal, gave cascara sagrada.

29th. No relapse; bowels regular.

CASE IV.—Girl, fifteen years old. (May 24, 1889.) Similar trouble two years ago; no cause found. Disease has lasted six weeks and is growing steadily worse. Now has chorea of arms and face; motions very sudden and sharp, of the kind often erroneously called electric. Has been treated with Fowler's solution, iron, and antipyrin. Gave sulphonal, 5 grains, three times daily.

May 31. Watched her for some time and saw no twitching. Medicine stopped. About four weeks later the trouble began again, but the further history is not known.

CASE V.—Girl, twelve years old. (June 1, 1889.) Two years ago began to shake and one eye became affected. No cause found. Internal squint; left external rectus weak; pupils react to light and accommodation. Heart and lungs normal; bowels regular; no difficulty with urination; marked chorea of left arm and left leg; knee-jerk absent; no atrophy, paresis, contracture, paræsthesia or anæsthesia. Gave sulphonal, 3 grains, three times daily.

June 6. Very slight improvement. Gave up sulphonal. With eyeglasses and Fowler's solution the patient improved until September 16th. She then returned with her glasses broken and general chorea.

Jan. 1, 1890. Still no better, in spite of glasses.

CASE VI.—Boy, four and a half years old. (June 5, 1889.) First attack. Had measles when six months old. Is the ninth of ten children, three of whom died of heart trouble following chorea. Father has chronic articular rheumatism. Disease began two weeks ago in the hands; now face, neck, speech, eyes, legs, bowels, and bladder are affected. Last night, for the first time, motion was noticed during sleep. Cross and restless; heart normal; has made no complaint of pain. Sulphonal, 3 grains, three times daily.

June 7. Better; sleeps well; added tinct. ferr. chlor., 3 minims, three times daily.

21st. Much better.

July 7. Slight if any motion. Has had no medicine for a week; iron alone given.

August 26. Is said to have slight motion if much excited. Has otorrhœa.

CASE VI.—Boy, fifteen years old. (June 26, 1889.) No family or personal history indicating the cause of his disease. Had chorea when three and again when thirteen years old. Pale; heart normal; chorea of hands, tongue, and throat. Sulphonal, 6 grains, three times daily.

July 1. No signs of chorea to-day.

5th. No signs of chorea, but has a slight tremor of voice if excited. Giddy. Stopped sulphonal, and gave Fowler's solution, 3 minims three times daily.

16th. Voice the same; otherwise well.

24th. Perfectly well.

CASE VIII.—Girl, twelve years old (June 25, 1889). First attack; no pains. Heart normal. Motion of arms, legs, face, and tongue. Gave sulphonal, 5 grains three times daily.

July 1. No better; changed to Fowler's solution, 5 minims three times daily.

5th. Has been vomiting. Chorea no better. Reduced Fowler's solution to 2½ minims, and added sulphonal 3 grains three times daily.

8th. Is quieter, and has had no more vomiting.

12th. Quieter; face swollen from a diseased tooth.

19th. Chorea worse; she twitches during sleep. Increased Fowler's solution to 5 minims, and gave potassium bromide 12 grains in place of sulphonal.

22d. Better, but the bromide has not improved sleep.

August 2. Worse. Fowler's solution in 7 minim doses; sulphonal, 2 grains.

7th. Same condition.

15th. Better; eyes began to swell, arsenic stopped. Sulphonal, 10 grains daily.

28th. Has been in the country one week. No traces of chorea.

Nov. 5, 1889. Since going to school relapsed for two weeks.

CASE IX. Girl five years old. (July 5, 1889.) First attack began seven weeks ago. Chorea of the entire body. Heart, bowels, bladder, and knee-jerk normal. Fowler's solution and sulphonal, 3 grains of each three times daily.

July 9. Chorea better, but has had much epistaxis and pain in the bowels. Stopped Fowler's solution.

17th. Chorea much better, no epistaxis, color not so good. Added iron to treatment.

August 2. Has had no medicine for five days and has been quiet for ten days.

26th. The patient came back from the country with some chorea. She steadily grew worse in spite of Fowler's solution and sulphonal until on September 7th she had a chill, epistaxis and great increase of chorea. The same occurred on both the following days in spite of quinine. On the afternoon of the 12th I made a microscopical examination of the blood and found numerous plasmodia malariæ. No enlargement of the spleen could be detected. Quinine was then given in very large doses, and no more chills occurred. Treatment since has been Fowler's solution in small doses, and now, October 24th, the child is a picture of health.[1]

CASE X.—Girl, eighteen years old. (July 7, 1889.) Chorea began after fright two days previously. Motion is confined to arms but is distinct and extensive. Heart normal. Knee-jerks almost abolished. Gave sulphonal, 5 grains, three times daily, and iron.

September 4. Patient returned a few times and has now been at work, and well, for a month.

The above are the first ten cases in which sulphonal was used of which I have records. In one other, in which a mitral murmur existed, endocarditis and fever came on in forty-eight hours, and the case was sent to the hospital. The cases are all called chorea on account of the typical motion and absence of symptoms pointing to other trouble, though I am far from sure that the ten cases are examples of one disease. Just before my term of service ended, I ordered sulphonal in two cases of chorea from imitation with, I understand, no beneficial results.

If sulphonal is found efficient in some of those cases where arsenic fails, or is not well tolerated, my expectations will be filled. In my experience sulphonal has proved more efficient than any other drug excepting arsenic. All my cases were also ordered a daily sponge bath, simple diet, and sleep in the middle of the day.

[1] The child was again taken with severe chorea on December 24th, and developed influenza a few days later. She was sent to the hospital.

THE TREATMENT OF CERTAIN FORMS OF GANGRENE OF THE INTESTINE.[1]

BY CHARLES B. PENROSE, M.D., PH.D.,
SURGEON TO THE GYNECEAN HOSPITAL; OUT-PATIENT SURGEON TO THE PENNSYLVANIA HOSPITAL, PHILADELPHIA.

I PROPOSE to consider briefly here the treatment of the degenerated or gangrenous condition of the intestine which is frequently met with in cases of pelvic or abdominal suppuration. In these cases the intestinal coats are destroyed by direct extension of the inflammation. The condition is common in tubal or pelvic abscess and in the perityphlitic abscess of appendicitis. In such cases we frequently find the abscess cavity walled in by adherent loops of intestine; the intestinal coats being in contact with the purulent accumulation and presenting on their surface one or more cheesy, degenerated spots, of a purple or black color, and from one-half to two inches in diameter. These spots often have in their centres perforations, generally of small calibre, but sufficiently large to permit of escape of pus by the bowel, and often of escape of fæces into the abscess cavity. A similar gangrenous condition of the intestine, with or without perforation, is sometimes present in the pelvic inflammatory troubles of women when the Fallopian tube effects adhesion by its fimbriated end to the sigmoid flexure or rectum, and may discharge its contents through this channel.

Another class of cases in which there is an analogous degenerated condition of intestine, and to which the following remarks with regard to treatment also apply, is found in intestinal obstruction, when the pressure upon the intestinal walls from within produces ulceration beginning in the mucous membrane and often extending through all the coats. Such ulceration has not, in my experience, been accompanied by the same amount of inflammatory infiltration and thickening of the diseased areas as occurs when the destructive process proceeds from without inward.

The condition of the patients in whom disease of this character occurs is generally such that they cannot withstand a prolonged or serious operation.

[1] Read before the Philadelphia County Medical Society, February 26, 1890.

Excision of the degenerated patches or resection of the intestine is in most cases out of the question. Evacuation of the abscess, removal of the exciting cause, and adjustment of the abdominal contents in positions most favorable for recovery, are the only steps to be considered. I will, therefore, leave all ideal surgical operations out of the discussion, and consider only those cases in which ideal surgery is impracticable. I will not discuss the best methods of removing the diseased portion of intestine, but the safest way in which it can be left in the abdomen. Such a discussion is of value because every surgeon must realize the impossibility of performing an ideal operation in many cases of abdominal surgery. Certain rules, theoretical or deduced from experiments on the healthy intestines of the lower animals, are laid down to be followed in the various abdominal operations on man, often without sufficient consideration of the pathological changes and distortions which may be caused by the disease that demands the operation. The determination of the extent to which one can go toward the ideal operation, without sacrificing any of the patient's chances of life to the surgeon's wish for mechanical perfection, distinguishes the true surgeon from the surgical mechanic. And to attain this end the surgeon must not only be familiar with the ideal operations possible in favorable cases, but also with the recuperative powers, and the best means to favor recuperation of diseased or injured structures in complicated cases where ideal surgery is impossible. In the disease, for instance, which is under consideration, the operator recognizes the danger of immediate, or not very remote, fæcal extravasation if the degenerative patches of intestine are not removed, or if the perforations or fistulous openings are not firmly closed, and yet he realizes that the patient may not withstand the ideal operations necessary for the accomplishment of this object. It is then that a knowledge of how much can be safely left untouched, and the best way of so leaving it, is most desirable.

When diseased intestine, such as we are considering, is left in the abdomen, our object should be:

1. To place it in a position which will tend most to favor its restoration to health.

2. To defer as long as possible the separation of the slough and the escape of fæces—if such an event is inevitable; or if a fistulous opening already exists, to defer the escape of fæces from this opening until preservative adhesions have taken place.

3. To place the intestine in a position most favorable for the spontaneous closure of a fistula, and most accessible for a subsequent operation.

4. To protect the sound peritoneum from infection from the diseased areas.

One of the most important points in the fulfilment of these indications is the adjustment of the diseased portion of intestine in a straight line, with the gangrenous patch facing the belly wall and in the immediate neighborhood of the abdominal incision. The straight position favors the easy passage of fæces past the gangrenous area, and it not only tends to prevent escape of fæces by reducing to a minimum the pressure from within, but it aids more than anything else the spontaneous closure of the fistula should one result. The easiest fistula to close is one situated on the side of a straight intestinal tube; the most difficult is one at the apex of a sharp flexure.

If the gangrenous spots face the abdominal wall the force of gravity will aid not only in preventing or delaying fæcal extravasation, but also in closing the fistulous opening. The value of gravity as an agent in the closure of a fistula is well illustrated by a case reported by Sir Henry Thompson, where an old urinary fistula which opened into the rectum was cured in a few weeks by making the patient pass his water while lying on his face. By placing the diseased portion of intestine near the abdominal incision we make it most accessible for drainage, we avoid the risk of a deep fistula, and we have it in a position easy for subsequent operation.

When fistulous openings exist in these gangrenous patches they are generally of small size; often so small that the escape of fæces and gas takes place only under pressure. In cases originating in pelvic or abdominal suppuration, the destruction of tissues proceeds from the outer to the inner coats of the intestine, and it generally happens that though pus may escape readily from the abscess into the bowel, yet the intestinal contents find a much less free exit on account of a valve-like closure of the opening. Some of these fistulous openings are so small that, existing as they do in the centre of a thickened diseased mass, they cease to be patulous when the intestine is freed from its adhesions, and are often not visible at the time of operation, their presence being proved only by the previous or subsequent history of the case. The firm closure of such fistulæ is impossible without excision of the whole gangrenous area and the coaptation of healthy tissues. None of the intestinal coats around the fistula will hold a suture of any degree of tension. The intestinal peritoneum cannot be dragged over the openings because it is rendered immovable by inflammatory adhesions, and is so friable that all sutures cut through. However, though these fistulæ cannot be firmly closed, yet the escape of fæces from them can be deferred for a considerable time. And this is especially true if the patient has been prepared for laparotomy by a thorough emptying of the intestinal tract. When the fistulous opening cannot be closed by sutures it may be covered by a large omental graft, extending around the intestine and reaching to the mesenteric attachment. Such a procedure

will delay, often for several days, the escape of fæces, and may result in cure without even the formation of a fistula.

There is a group of cases in which the gangrenous intestine and the fæcal fistula are situated in a position not accessible for operation. This occurs in cases of pelvic suppuration with the history of purulent discharge from the anus. The fistula exists in the rectum, or in the sigmoid, which is often as inaccessible for operation as the rectum on account of adhesion and contraction of the mesocolon. Under such circumstances all operations for closing the fistula are generally out of the question.

It is, however, fortunately situated in a position most favorable for spontaneous cure, being on the side of a straight portion of intestine, more or less immovable, and especially accessible to drainage and irrigation from above and to intestinal drainage and disinfection through the rectum. Indeed, in most cases small rectal fistulæ—if properly treated—in no way interfere with the patient's chances of recovery, even though left unclosed.

To insure the spontaneous cure of fistulæ it is important that there should be no obstruction in the distal portion of the intestine. All obstructing inflammatory tissue and bands of adhesion must be completely removed, and intestine adherent in sharp flexures must be straightened out. We thus obey a most important rule for the closure of all fistulæ, by rendering the natural passage-way the easier one.

Of course, in all cases of gangrene of the intestine drainage is of the greatest importance, especially drainage by means of large straight tubes whenever we fear escape of fæces. Care must be exercised in placing the drainage tubes, that they do not exert any lateral or vertical pressure upon the diseased portion of intestine, as sloughing has occurred from this cause even in healthy structures.

Before concluding I will report briefly three cases of gangrene of the intestine, in which ideal surgical operations were impracticable, and which were cured by treatment such as I have been considering.

Case I. *Abdominal and pelvic abscess, gangrenous intestine, entero-vaginal fistula.*—C. G., twenty-one years old, had a history of syphilis of two years' duration. Abdominal section was performed for double hydrosalpinx, and at this operation the peritoneum and the intestines were found perfectly normal with the exception of some healthy pelvic adhesions. Eight days subsequently it was necessary to reopen the abdomen on account of symptoms of intestinal obstruction, and because it was discovered that a free discharge of fæces was taking place through the vagina. At the second operation the peritoneum was in the following condition: There was an abscess in the right inguinal region containing several ounces of pus. In immediate contact with this accumulation was a loop of small intestine eighteen inches long. The whole loop was thickened, stiff, and friable. On the convex surface were two black, necrotic patches two inches in diameter. A second collection of pus was found behind the left broad ligament. The sigmoid was in contact with this accumulation, and was firmly adherent to the posterior wall of the vagina. When separated from the vagina the bowel presented on its surface a necrotic patch one and one-half inches in diameter. The fistulous opening through which fæces had escaped into the vagina existed in the centre of this patch as there were no other portions of the intestine adherent to the vagina. The opening, however, was not patulous, and was obscured by the thickened diseased tissues around it.

As the patient was in a condition of collapse, with an almost imperceptible pulse of 160, no radical procedure like resection or excision could be performed. The gangrenous spots were, therefore, left untouched. The small intestine was placed transversely across the abdomen, immediately above the upper angle of the incision. The sigmoid was freed from all adhesions and straightened as much as possible, and the abdomen was drained by means of three tubes through which continued irrigation was conducted. The patient recovered perfectly without at any time having escape of fæces by any but the natural passage. This is especially remarkable because there was left unclosed a fistulous opening which had been large enough to permit the free escape of fæces into the vagina before operation.

Case II. *Abdominal abscess, gangrenous intestine.*—A. H. had been suffering for several years with pelvic pain, and recently with acute abdominal trouble with great pain, chills, hectic, uncontrollable nausea, diarrhœa, very free discharge of pus and blood by the rectum, and rapidly increasing emaciation. At the time of operation the abdomen was distended and tender, with marked fulness and feeling of resistance, and dulness on percussion over the right side from the groin to above the umbilicus. Temperature 103°, and pulse 130. Median laparotomy was performed and almost a quart of feculent pus was evacuated from an abscess cavity in the right side of the abdomen, which extended from the floor of the pelvis to two inches above the umbilicus, and inward to the median line. At the bottom of this cavity was found a pyosalpinx, which had been the cause of the trouble. Though a large mass of intestine walled in this collection of pus, yet there was but one gangrenous spot discovered. It was on a loop of ileum and was about two inches in diameter. No fistula was detected, though it is probable that a small valvular opening existed in this spot, as there had been a free purulent discharge from the bowel before operation. As the removal of the necrotic patch was impossible without resection, it was covered by a large omental graft. The intestine was placed in a straight line transversely across the abdomen, with the gangrenous portion at the upper angle of the incision; and two glass drainage tubes were introduced, one to drain the healthy peritoneum and the other the site of the purulent accumulation.

Pulse after the operation was 160. On the fourth

day fæces escaped from the larger tube, viz., the one which drained the right inguinal region. The quantity increased daily until at the end of a week the total discharge of the bowel came through the abdominal incision. After this it gradually decreased, and six weeks after the operation the abdominal wound was firmly closed and all fæces passed *per anum*. The woman is now in good health.

CASE III. *Gonorrhœal pyosalpinx, with a fistulous opening into the rectum.*—A. F. had been suffering with pelvic pain for three years. For several weeks before operation she had been unable to stand erect, and had frequent discharges of small quantities of pus from the anus. After each discharge the pain was temporarily relieved. Abdominal section was performed and two pus tubes were removed. There was no abscess in the pelvis outside of the Fallopian tubes. The right tube was adherent by its fimbriated end, low down on the anterior surface of the rectum. The discharge of pus had taken place at this point. Fæcal odor was perceived after removal of the tubes and irrigation of the pelvis. There was, however, no escape of fæces until the gla-s drainage tube was introduced, when a small quantity of dry fæces was withdrawn through the tube by a syringe. The woman was unusually large and fat, and the fistula could not be brought into view, and was inaccessible for any attempt at closure. No such attempt was therefore made, reliance being placed altogether on the abdominal drainage tube, and on drainage through a glass tube inserted in the anus. I felt especially confident in leaving the fistula patulous, since the woman had been thoroughly purged for two days prior to the operation; and because it was in a position most favorable for spontaneous closure.

There was no discharge of fæces from the abdominal drainage tube until twenty-four hours after the operation, when the nurse, without direction, administered a turpentine enema, the result of which was intense pain throughout the lower half of the abdomen and the free escape of turpentine and water from the abdominal tube. For four days after this there was a feculent discharge from the abdomen, and on the fifth day a large quantity of flatus escaped through the abdominal tube while the rectal tube was removed for cleansing. The bowels were moved by glycerin enemata on the ninth day, everything coming by the natural passage. The patient was discharged cured four weeks after the operation.

I have reported these cases because they illustrate the pathological condition to which I wish to call attention, and because they show what can be done without resort to the most heroic surgical operations. In conclusion, I will repeat what seem to me to be the most important points in the treatment of such cases:

1. Free purgation of the patient before operation.

2. Complete removal of all obstructing causes below the gangrenous intestine.

3. The adjustment of the gangrenous intestine in a straight line.

4. Thorough drainage and irrigation of the peritoneum.

THE LEGAL ASPECTS OF VIVISECTION.

BY JAMES M. BECK,
OF THE PHILADELPHIA BAR.

THE recent case of Commonwealth *vs.* Benjamin T. Shimwell, M.D., who was charged with cruelty to animals in vivisecting a dog for scientific purposes, is interesting, not only because it is believed to be the first case of its kind on either side of the Atlantic, but also as it illustrates the legal position taken by the Society for the Prevention of Cruelty to Animals with reference to vivisection. It may, therefore, serve as an apology for a short article upon the legal aspects of vivisection, although the writer must first disclaim any intention to discuss its propriety as a subject for legislation. The theme must simply be the application of the English common law, and of the general statutes prohibiting cruelty to animals, to vivisection.

Dr. Shimwell was arrested under the Act of March 29, 1869, which provides that if "any person wantonly or cruelly ill-treats, overloads, beats, or otherwise abuses any animal, whether belonging to himself or otherwise, shall be deemed guilty of a misdemeanor." The facts adduced at the hearing showed that in order to demonstrate to a class of students in the Medico-Chirurgical College of Philadelphia the value of Dr. Senn's new method of intestinal resection, and of some original and improved methods of performing it, Dr. Shimwell, after thoroughly etherizing a dog, operated upon it and kept it alive for a number of days, in order to note the success or failure of the experiment. It was not disputed that, so far as the operation permitted, the same care was taken with the dog as with a human being, to spare it unnecessary pain and to save its life.

The Society, at whose instance the prosecution was commenced, did not dispute that if the operation had never been attempted, or its success demonstrated, the use of the animal in the interest of science was not cruelty under the Act quoted. Its contention, in the language of one of the witnesses (Dr. Wistar), was that "if the operation had been performed upon inferior animals, and demonstrated as being a possible operation from which they will recover, then the necessity for vivisection ceases." The Doctor did not think, on cross-examination, that vivisection was justifiable for the purpose either of class demonstration or to gain dexterity. In his judgment, the cadaver served the purpose equally well, and, when the witness was asked when research ceased to be original, he thought that if any physician of reputation published the success of a novel surgical operation, the profession was not only justified in accepting the theory, but was precluded from testing its merits by vivisectional experiments. This was the position assumed by the learned Doctor

and the attorney for the S. P. C. A. Of its scientific correctness the profession must judge. The writer will only discuss its legal merits.

We must first resort to that unwritten body of usages which forms the foundation of our law in England and America, known as the common law. It gave man an absolute and unlimited control over his personal property. It and the Mosaic law declared with equal emphasis that man had, by the gift of the Creator, "dominion over the fish of the sea and over the fowl of the air, and over every living thing that moveth upon the earth."

While any one who maimed an animal belonging to another could be indicted at common law for *malicious mischief*, the gravamen of the charge was the invasion of the owner's right of property, and not the cruelty to the animal, for the animal having no rights at law, none could be invaded. Therefore, as a man could cut down his own tree, at such time and in such manner as it pleased him, without reference to his motive or wisdom in so doing, so he could maim or kill his animal for any purpose whatever. Like the good man of the house, he would say: "Can I not do as I will with mine own?" Therefore, the slaughter of animals for food, for clothing, for sport, or for any other purpose, was recognized and upheld.

Then Mr. Bishop, in his very able treatise on criminal law, says: "The common law recognizes as indictable no wrong, and punishes no act of cruelty, which they (the lower animals) may suffer, however wanton and unnecessary." The apparent exceptions to the rule have arisen in which the cruelty was either so public as to amount to a nuisance, or immoral in its tendency. In these cases it is not the brute whose rights are infringed, but the public, whose quiet and well-being are attacked.

In State of New Jersey *vs.* Beekman (3 Dutcher, 124), the defendant was indicted at common law for wounding a cow, the property of another. It was held, on an elaborate opinion by the Chief Justice, that no such offence existed at common law, and the prisoner was discharged. A number of English cases, stating the same doctrine, are referred to in vol. 2 of East's *Pleas of the Crown*. Indeed, the judges who declared the law, with the wool of sheep upon their backs, and (if we are to believe the great poet) their bellies "with good capon lined," could not well have stated it otherwise.

The importance of this consists in the fact that the anti-vivisectionists, in order to interfere with the rights of property at common law, and the individual's personal liberties, must show an express legislative enactment, and such enactment, being in derogation of the common law, and in this case criminal, will be construed strictly against the prosecution and in favor of the liberty of the subject.

The first English statute "to prevent the cruel and improper treatment of cattle," was passed in 1822, and "punishes any one who wantonly and cruelly beats, abuses, or illtreats any horse, mare . . . . or other cattle." This and the subsequent English statutes are so similar in form and language to the Pennsylvania statute above quoted, that their full recital is unnecessary, except to add that English legislation so fully recognized the inapplicability of them and of the common law to vivisection, that a special statute was in recent years passed, in a temporary aberration of the legislative mind, to prohibit it.

A brief reference to the decisions on these and similar statutes will show that a uniform principle runs through them all. They were not intended to make animals less serviceable to man, nor to abridge his right to beat or kill them for proper purposes. Pain or death inflicted upon the animal is only illegal when cruel, and cruelty has been defined by the Lord Chief Justice of England as meaning "cruelty without reason, cruelty in making one of the lower animals suffer without any reasonable object or to an unreasonable extent." As there must always be, to secure a criminal conviction, a criminal intent, it necessarily follows that when pain or death is inflicted upon an animal, not in a wanton spirit to inflict pain, but in good faith for the benefit of man, there can be no conviction. It may well be that the use designed may not be a useful one, but if the owner in good faith believes it to be, he is protected. It is the wanton or wilful cruelty that is alone punishable. Thus Judge Hoar, in a Massachusetts case, in which a man was arrested for cruelty to a horse, says: "It certainly is not true as an abstract proposition that it is immaterial what may be the motive of a person who inflicts pain upon an animal. Pain inflicted for a lawful purpose and with a justifiable intent, though severe, does not come within the statute meaning of cruelty.

"Thus *a surgical operation*, occasioning the most intense pain, may be justifiable, and is not criminal. To drive a horse at a rate of speed distressing to the brute, *when the object is to save human life*, or to attain any other object of adequate importance, may be lawful." (Commonwealth *vs.* Lupkin, 7 Allen, 579.) In the case of State of New Hampshire *vs.* Avery (44 N. H. 396), where a man was charged with cruelty in beating a horse, and the defence was that the beating was in the course of training, Judge Bellows said: "If it (the alleged cruelty) was resorted to in good faith, and for a proper purpose, it will not be necessarily malicious." In a New York case, where a dog was used in a treadmill, and this was contended to be an improper use, Judge Davis said: "Although a dog is not a beast of burden, yet it is not cruelty to train and subject him to any

useful purpose. His use in any mode by which his strength and docility may be made serviceable to man is commendable, and not criminal."

A reference to the English cases shows that a similar principle prevails in Great Britain, notwithstanding that Parliament has declared against the practice of vivisection. In the case of Murphy *vs.* Manning (2 Exch. Div., L. R. 307) defendant was arraigned for cutting the combs of cocks in order to fit them for cock-fighting. He was adjudged guilty on the express ground that cock-fighting was illegal, and that therefore the pain was inflicted for an unlawful purpose. Judge Kelly said, in delivering the opinion of the Court: "There are some acts which are cruel (*i. e.*, painful) in the extreme, and no legislation can make them otherwise, yet they are perfectly lawful, and not within the Act because they are done for some lawful purpose. . . . As it (cock-fighting) does not better fit the animal for the use of man, or for any other lawful or proper purpose, it is wholly unjustifiable."

The case of Lewis *vs.* Fermor (18 L. R., Q. B. D. 532) is a strong case against the anti-vivisectionists. In this case certain sows were spayed—that is, the uterus and ovaries were removed, because the flesh of the animal deteriorated in its periods of heat. No anæsthetic was used, and the operation caused pain. The object desired was an increased pecuniary profit, and the end desired was not strictly necessary, as it was admitted that the same end could be attained by killing the animal when not in heat. The defence was that the operation was not wanton, but done in good faith. Said Judge Day: "It seems to me that cruelty means the infliction of grievous pain without a legitimate object, either existing in truth or *honestly believed in*." Said Judge Wills: "The Act should receive a fair and reasonable construction so as not to bring within the criminal law people who act honestly and without any evil mind or motive. . . . I think there must be something of a moral element of cruelty to bring the case within the section. The question is, whether the act was done for a lawful purpose, and not whether, in point of fact, in the opinion of the tribunal that has had to adjudicate, the practice is a good one. . . . In my opinion, if a person who performs the operation entertains an honest belief that what is done will benefit the animal, he is not liable to be convicted."

The belief may sometimes be erroneous, but we must be careful that we do not try to teach new, though perhaps improved, views on matters within the area of fair scientific discussion, by means of the criminal law. The question has chiefly arisen in a number of cases in which cattle were dishorned. In these cases it appeared that the operation caused intense pain, that it was only practised in certain parts of England and Ireland, and that tipping the horns would accomplish the same result—*i. e.*, the prevention of goring—without the infliction of pain. On the contrary, it was shown that the operation made the animals more docile, and cost the owners less to stall, and enhanced their value. Under these facts, the Scotch courts (15 *Judiciary Cases*, 84) held the practice not to be cruelty within a similar Act, and justifiable under the circumstances. The Irish courts, in Callaghan *vs.* S. P. C. A. (16 L. R. (Ir.), 325) reached the same conclusion. In the former case Lord Young said that the statute must not be construed to "interfere with the judgment of those who are pursuing their own affairs to the best of their judgment, however much they may be mistaken in the judgment of others." In the Irish case, Morris, C. J., said: "Looking at the suffering in reference to the object with which it is inflicted, it cannot in my mind be considered as unnecessary, for the object is reasonable and adequate."

The same practice came before the Judges of the English Queen's Bench Division, and they, in the very latest case, dissented from the Scotch and Irish courts upon the facts, but Lord Chief Justice Coleridge says: "Necessity, to form an excuse under the statute, does not mean simply that the effect of an operation cannot be otherwise secured. *There must be a proportion between the object and the means.* Mutilation of horses and bulls is necessary, and undoubtedly lawful." Said Judge Hawkins: "The beneficial or useful end sought to be attained must be reasonably proportionate to the extent of the suffering caused."

Applying the principle of these cases to vivisection, it may be safely affirmed that the distinction sought to be made in the Shimwell case between original research and class demonstration is untenable. If vivisection substantially adds to the ever-growing fund of human knowledge (and who can question it?), or if it enables the professor to demonstrate more thoroughly the value or danger of particular operations to his class, or if the practitioner substantially adds to his dexterity and skill by its use, it is, on either of these grounds, legally justifiable, and is not "cruelty" in the legal meaning of the word. If, to add to the pecuniary value of sows and other cattle, it be justifiable to mutilate them, how unjustifiable is a prosecution that seeks to bring within the pale of the criminal law a scientist who for the good of his fellow-men, and with every precaution to spare the animal unnecessary pain, sacrificed it upon the high altar of science?

The Royal Ophthalmologist.—The ophthalmologist, Prince Carl Theodor, of Bavaria, proposes to establish an eye clinic near Munich, similar to that which he has conducted at Tegernsee, and the hospital at Schwabing will afford all the accommodation required at the outset.

CLINICAL MEMORANDA.

THERAPEUTICAL.

Cod-liver Oil Emulsion.—Cod-liver oil emulsions, in various forms, are preparations which have of late become somewhat popular. I express no opinion whatever on any of these preparations, far less do I intend to individualize any preparation by attempting to give a copy of the formula. I simply recognize the unfortunate necessity which sometimes arises of following where our inclination does not lead, and I therefore give a formula for an emulsion, believing it, without prejudice, equal to any of the many now before the profession and the public.

Of all the excipients suggested by different authorities as well as commending themselves to one's own approval for emulsifying cod-liver oil, none, I think, equals gum tragacanth. Without, therefore, ignoring other substances, such as mucilage of gum arabic, white of egg, alkaline solutions, and so on, I have principally endeavored to ascertain the conditions most favorable to produce with tragacanth an inseparable emulsion, which, at the same time, would be miscible with water, contain a reasonable amount of oil, and be not particularly objectionable in appearance, taste, or smell. Of course, in all these preparations, much may be left to individual fancy as to combination; and I, therefore, make no suggestion as to all the different ingredients which may be added, further than this, that if oil of bitter almond be the flavoring agent used, both experience and experiment have determined that a half per cent., or about two drops to each ounce of cod-liver oil, is the proper proportion; and that of the two oils, namely, an oil deprived of its hydrocyanic acid, or an oil containing it, the latter is preferable.

As to the emulsion, let three drachms of the finest white powdered tragacanth be rubbed up in a large mortar with three ounces of glycerin, to this add as much boiling water as will convert it into a thick, transparent jelly, from eight to ten ounces probably being required. After cooling add the cod-liver oil, which should first be mixed either with plain water or lime-water, in the proportion of one of the latter to three of the oil; or, if the emulsion is intended to contain the hypophosphites of lime or soda, let these be added to the plain water previous to mixing with the oil, and then let this primary emulsion be gradually added to the mucilage of tragacanth with constant stirring. In the process of mixing, the emulsion not only creams but also thickens up to a certain point; the individual taste must settle the extent to which the mixture may be carried. I have found the three drachms of tragacanth emulsify from fifty to eighty ounces of what I have called the primary emulsion, the former quantity being very thick and not easily poured from the mortar, the latter quantity flowing more freely and forming what I consider the better emulsion. In mixing the oil with the mucilage of tragacanth, care must be taken not to add it too hurriedly, else it will not emulsify; the mixture will simply break up into a clotted mass, and no amount of labor, apparently, will bring it back to the emulsified form. Under these circumstances, the better way is at once to begin again with a small quantity of fresh mucilage, to which the clotted mass should be carefully added by degrees. In this way only can the emulsion be brought back to its proper form.

HERBERT GRAHAM,
FORT WARREN, BOSTON, MASS. Hospital Steward, U. S. A.

HOSPITAL NOTES.

PRURIGO. ECZEMA RUBRUM. MOLLUSCUM CONTAGIOSUM.

Abstract of a Clinical Lecture
Delivered at the New York Post-Graduate Medical School.

BY ROBERT W. TAYLOR, M.D.,
PROFESSOR OF DERMATOLOGY.

DR. TAYLOR said that he intended to present to the class a typical example of a disease which has not been very well understood in this country, where it hitherto has been looked upon as a great rarity. It is all-important to be familiar with it, as the general practitioner is much more liable than the dermatologist to meet with it, particularly in the early stages. In this country we have been so sceptical about it that undoubtedly cases have been observed which were erroneously considered as eczema, ecthyma, urticaria, or impetigo. The disease under consideration is known as the prurigo of Hebra. It was first described by Willan as prurigo, and his description was elaborated by Hebra, who gave an unexcelled clinical history of a more exaggerated form of the disease. In this lecture we shall consider the two diseases—the prurigo mitis of Willan, and the prurigo ferox of Hebra.

During more than twenty years, cases of the so-called prurigo of Hebra have been presented to the New York Dermatological Society; but the members of that body had such an abiding impression that the disease was exceedingly rare, that they received these cases with derision, and the men who presented them, not feeling positive of their diagnosis, have not been bold enough to withstand this opposition. It must be remembered, also, that as these cases were seen at night, many of the papules and other lesions may have been unnoticed.

At a meeting of the American Dermatological Association, in Boston, last September, a very intelligent dermatologist of Chicago, Dr. Zeisler, read a paper, in which he asserted that he had seen quite a number of cases—at least twelve—of this disease. The members marvelled that this young man should have seen in a few years so many cases—almost as many as all the other American dermatologists combined had seen. It so happened that Drs. Bowen and Tilden, of Boston, also presented a good case of prurigo. After thinking over the matter, Dr. Taylor had recalled three cases which he had seen—two in children, and one in a man—and the other members in like manner were able to recall a few examples of this disease.

The disease is not infrequent in Europe, but here it has been considered exceedingly uncommon. A careful examination of the literature of this subject would probably show that not more than fifty cases had been observed up to the present time in America.

CASE I.—Dr. Taylor then presented an eight-year-old girl, who is said to have had prurigo for four years. It is highly probable that she has had it much longer, and that, owing to its insidious onset, it had not been noticed.

The disease is never congenital, but commonly begins before the patient reaches the age of two years. According to Hebra, it is a disease which ceases only with death, and his writings lead us to suppose that many of the older subjects, made desperate by their prolonged suffering, are driven to suicide.

When the eruption began in this child, it was thought to be only mosquito-bites. This is the usual story; the patients are either thought to suffer from insect bites or urticaria, and the family physician, ignorant of the serious nature of the disease, usually agrees with the parents as to the insignificant character of the eruption.

Some cases appear to be in their usual health, but many are evidently anæmic, or become so with the progress of the disease. The amount of anæmia or cachexia will usually be proportionate to the extent and intensity of the pruriginous disease, and also to the social conditions of the patients, who usually belong to the poorer class.

So far, this patient has not suffered very much, for we are told that she does not scratch very much, except at night. This case is no exception to the rule that when the patient is much out-of-doors, and perspiring freely, as in summer, the disease is temporarily held in abeyance. Crocker, of London, noticed that the disease was better in winter than in summer; but his experience is opposed to that of every other dermatologist.

The child's face presents an admirable picture of the prurigo. The pale facies is characteristic; some of the papules are whiter than the skin; others are yellowish, and they vary in size from a small to a large pin's head. The papules are conical, and the eruption shows one feature which Hebra insisted upon—*i. e.*, that the head and nucha are not involved, but the papules begin to develop where the shoulders merge into the neck. The dried blood-crusts on the apices of some of these papules show that they have been scratched fiercely. These patients usually scratch the scalp a good deal, and the hair becomes dry and rough, but not very scurfy. The eruption extends from the roots of the fingers to the elbow, and the disease has been localized for a number of years upon the extensor surface of the forearm, entirely sparing the bend of the elbow, and is now throwing out a number of scattered papules on the flexor surface, and spreading upon the arm by the same mode of development and distribution of these lesions. The papules are abundant on the forearms, scattered without order, and are not grouped in any way. The disease has skipped from the shoulders to the buttocks, where the papules are more sparsely distributed; and the scratch-marks and blood-crusts on these regions tell the story of vigorous scratching. The eruption is not present in the popliteal region, but on the outer and posterior portion of the leg one finds some whitish, conical, and crust-covered papules. The papules here are seen to be quite large, owing to the hyperæmia and cell increase which result from the scratching. Ordinarily, the papules, as stated, vary in size from that of a hemp-seed to that of the head of a large pin. The thighs are entirely free from the disease.

The glands in the neck are very much enlarged, and the epitrochlear and inguinal are also increased in size, but to a less extent. The amount of adenopathy is usually in proportion to the duration, extent, and severity of the disease; so that when the patient reaches the age of puberty, these glands, particularly in the groin and over Scarpa's triangle, are hard and nodular, and may be as large as one's fist.

The primary lesion in this disease is an effusion of serum and leucocytes, from the upper layer of vesicles, into the substance of the papillæ; and the papules, although not so superficial, resemble vesicles in thus containing serum, which, however, is present rather low down in the corium. The effusion of serum is the result of an inflammatory process, which gives rise to hyperplasia of the papillary body, thickening of the whole epidermal structure, and of the rete, with pigmentation of the latter. The case before the class shows this yellowish brown pigmentation on the hands, as a result of the hyperæmia produced by scratching; and if the disease be not arrested, the deposit of pigment will continue until the skin will become as dark as that of a mulatto. As another result of the inflammatory process and of scratching, one will notice an entire absence of lanugo on the back of the hand; and also that the natural furrows of the skin are greatly enlarged, as is best shown about the wrists of this patient.

Sometimes the papules are not visible, but by passing the finger with firm pressure over the skin, one can readily detect the peculiar shot-like feeling of the skin.

So far, there have been presented the clinical features of a typical and uncomplicated case of prurigo. But the disease is often complicated, and in a measure masked by urticaria, eczema, or by the occurrence of furuncles, ecthymatous pustules and ulcers, or by an impetiginous condition. In such cases inquire into the early history, and remember that prurigo begins, when the child is young, with so-called flea-bites upon the extremities, and that it is attended with great itching, usually from the beginning.

It is probable that in very many cases prurigo begins as an urticaria, which is the outward and visible sign of dyspepsia; and the gastro-intestinal troubles are the cause of the urticaria or papular erythema, which is, in turn, the starting-point of the prurigo.

Treatment.—This naturally leads to the question of prophylaxis, and enforces the practical deduction that great attention must be given to the diet of the children who are the subjects of recurrent urticarial or papulo-erythematous eruptions. All causes of gastro-intestinal irritation must be removed on account of the powerful influence which they exert, by reflex action, upon the skin in the production of inflammation. Having secured a healthy condition of the digestive tract, the next thing is to see that nothing irritating comes against the skin. This child has on merino underwear, which is very good; but the rough stockings are very bad. No flannel should come in contact with the skin. Apply dusting powder to all chafes, and avoid the use of too much bed-clothing. Quinine and arsenic have proved ineffective; cod-liver oil is useful in most cases where it is well borne by the stomach; in the present instance it would be well to give two or three grains of the ammonio-citrate of iron three times a day. Quinine should be carefully avoided in prurigo, since it often causes congestion and irritation of the skin and an exaggeration of the pruriginous eruption.

The best local treatment consists in the use of warm alkaline baths (90° to 96°), followed by an inunction

with 5 per cent. carbolized vaseline. The next day, it is a good plan to make use of inunctions with vaseline, sweet or almond oil, applied three times a day, with a view of preventing the dryness of the skin so common in these cases. The various antiparasiticides—*e. g.*, the tars, carbolic acid, cocaine muriate, peppermint, camphor, etc., may be employed, and Kaposi considers naphthol very valuable; but Dr. Taylor thinks the alkaline baths and inunctions are more beneficial.

Case II.—The next case was a baby four months old with eczema rubrum of the face. It began as a small spot on the ear, which was washed and irritated until this eruption developed, which involves the forehead and both cheeks, resembling a mask. The patient presents a typical picture of that form of scaly eczema which Unna calls seborrheic eczema. The eruption develops anywhere where there is pressure, moisture, or irritation, as on the nates and in the popliteal spaces. The impress made upon the system by this original eczema constitutes a morbid tendency in the skin itself. It is not, as the older writers used to consider, due to a diathesis. Debilitated children are more liable to inflammatory processes, and some children have more delicate skins than others. The child's skin is very susceptible to inflammation, for it is soft and succulent, and contains young cells undergoing very rapid growth, and peculiarly prone to inflammation.

Treatment.—Stop the washing, and remove all other sources of irritation. If the adjacent parts must be washed, let it be done with a lotion consisting of one part of bay rum to four parts of water, lightly sopped on the affected parts. Internal medication may be required, but external treatment is usually competent to effect a rapid cure. For the patches on the face and arm, nothing is better than the following, which is to be smeared over the face, and will remain on the parts like a paste:

R.—Camphor		15 grains.
Calomel		½ drachm.
Starch, Zinc oxide	of each	2 drachms.
Vaseline		½ ounce.—M.

Never use this paste or the oxide of zinc ointment upon the scalp or palms, for it is too drying. In all these cases it is well to give, every three or four days, a powder containing one or two grains of calomel, and to avoid all sources of gastro-intestinal irritation.

Case III.—The next patient was a child four and a half years of age, who has had an eruption for the last two months about the eyes and neck. It consists of little yellowish and pinkish sessile and pedunculated tumors, scattered over the upper eyelid and near the canthus on the right side, on both the left eyelids, and of two larger isolated tumors on the chin and over the notch of the sternum respectively. This disease is variously designated as molluscum contagiosum, molluscum epitheliale, molluscum simplex, and molluscum sebaceum. There is still a want of unanimity of opinion as to the structure of these little tumors, some thinking they are connected with the sebaceous glands, while others say they have no connection whatever with these glands, but are formed from the cells of the rete. The question of the contagiousness of this disease is still in dispute, although a case was recently reported in France, in which material was said to have been rubbed from one child to another, causing the disease; but the volume of testimony is against its being contagious, and conflicting testimony may be explained by insufficient and incorrect observation, or by coincidences.

The disease is most commonly found in young children, but it is also met on the penis, scrotum, and female breasts and external genitals of adults.

Treatment.—The smaller tumors can be readily destroyed by the electrolytic needle; while larger ones should be bisected, their contents squeezed out, all ragged tissue cut away, and antiseptic healing promoted by dusting the surface with iodoform or boric acid. In certain localities they may be snipped off with scissors or ligated. In this case chloroform or ether narcosis would be necessary before the removal of the tumors about the eye could be attempted.

In some cases the disease is very extensive; Dr. Taylor said that he had a photograph of a child on whom were between two and three thousand of these little growths.

If left alone they wither and form small tumors called nævus mollusciformis.

MEDICAL PROGRESS.

Diet in Diseases of the Kidney.—Dujardin-Beaumetz assumes that in disease of the kidney with insufficient secretion of urine it is of primary importance to prevent the formation of toxic ptomaines in the digestive tract. This is attained by the administration of intestinal antiseptics, such as naphthalin and the salicin compounds, and a carefully regulated diet. The flesh of animals and fish, particularly if not fresh, always contain ptomaines, and hence should be interdicted, or, if used at all, must be absolutely fresh and thoroughly cooked. For the same reason old cheese should not be taken. The nourishment should consist chiefly of hard-boiled eggs and such vegetables as beans, peas, lentils, and potatoes, which may be made into a thick soup. Green vegetables may be used and also mush made from corn, barley, or oats. Fruit may be eaten freely. The drink should consist of milk or light beer. White wine well diluted with water may be occasionally used.—*Prager medizinische Wochenschrift*, February 19, 1890.

Prescription for Chronic Rheumatism.—The *Kansas City Medical Index* quotes the following as a favorite prescription of the late Dr. Fothergill for chronic rheumatism:

R.—Arsenious acid	3 grains.
Pulverized guaiac	3 drachms.
" capsicum	½ drachm.
Pill of aloes and asafœtida	3 drachms.

Mix and divide into 120 pills, of which one should be taken three times daily.

Hypodermic Injections of Thymolate of Mercury in Syphilis. The excellent effects obtained by Jadassohn and Zeising in the treatment of syphilis by subcutaneous injections of the thymolate and the salicylate of mercury are confirmed by Welander (*Centralblatt für klinische Medi-*

cine, February 22, 1890) who has made a number of injections with the acid thymolate (one part in ten parts of liquid paraffin). The pain of the injections is trifling, but more or less infiltration usually occurs at the seat of injection. In one case a trace of albumen was found in the urine during treatment. In all cases mercury was found in the urine, its first appearance varying from two hours to several days after the first injection. Mercury continues to appear in the urine for some days; in one case it was found one hundred days after the last injection. Welander prefers the thymolate to the salicylate, as in his experience it causes less pain and infiltration than the latter.

New Operation for the Radical Cure of Hernia.—DR. WILLIAM S. HALSTEAD, of Baltimore, has recently reported in the *Johns Hopkins Hospital Bulletin* five cases of hernia treated by the following method:

1. The incision begins at the external abdominal ring, and ends one inch (less than one inch in children) to the inner side of the anterior spine of the ilium on an imaginary line drawn through the anterior superior spines of the ilia. Throughout the entire length of the incision everything superficial to the peritoneum is cut through.

2. The vas deferens, with its vessels, is carefully isolated up to the outer termination of the incision, and held aside.

3. The sac is opened and dissected from the tissues which envelop it.

4. The abdominal cavity is closed by quilted sutures passed through the peritoneum one and one-half to two inches above the so-called neck of the sac.

5. The vas deferens and its vessels are transplanted to the upper angle of the wound.

6. Interrupted, strong silk sutures, passed so as to include everything between the skin and the peritoneum, are used to close the deeper portion of the wound, which is sewed from the crest of the pubes to the upper outer angle of the incision. The cord now lies superficial to these sutures and emerges through the abdominal muscles about one inch to the inner side of the anterior superior spine of the ilium.

7. The skin is united over the cord by interrupted stitches of very fine silk. These stitches do not perforate the skin, and when tied they become buried. They are inserted in the under side of the skin, and made to include only the deeper layers—the layers which are not occupied by sebaceous follicles. Thus infection of the sutures from organisms which may be present in the follicles is avoided.

8. One or two small, short gauze plugs are used as wound drains.

The immediate result in all the cases reported was good. Three of the patients were children, two adults. Sufficient time has not yet elapsed to test the ultimate results.—*Annals of Surgery*, March, 1890.

The Treatment of Acne.—In a recent lecture on acne, DR. J. FRANK PAYNE (*Lancet*, February 15, 1890) gave the following advice upon the treatment of the disease: Patients should be told to wash the parts at night with hot water and strong soap—soft-soap in small quantities if the skin is thickened. Friction with a towel should follow the washing. If the comedones are abundant and not removed by the washing and friction, they may be squeezed out with a suitable instrument. Washing should precede the expression, and a lotion should be applied immediately afterward. In acne vulgaris this should be supplemented by certain drugs, of which sulphur is the most useful. Absolutely dry sulphur does not affect the tissues at all, and it is most efficacious when combined with an alkali. An excellent alkaline sulphur lotion is as follows:

R.—Precipitated sulphur	15 grains.
Glycerin	½ drachm.
Spirit of camphor	5 minims.
Lime-water	1 ounce.—M.

For some skins the lime-water is too strong, and the mixture may be diluted with rose-water. This should be applied at night with a soft sponge or pledget of cotton, allowed to dry, and washed off in the morning. The usual sulphur ointments are too strong; 15 grains of sulphur to an ounce of soft paraffin or benzoated lard, to which may be added 10 minims of carbolic acid, is of the proper strength and forms a useful application. To make this alkaline, 15 grains of potassium carbonate may be added.

This treatment, though it may not entirely remove the disease in young persons, will cure the attacks as they recur. Another excellent application is the following:

R.—Corrosive sublimate	½ grain.
Emulsion of almond oil	1 ounce.—M.

Lead or zinc mixtures may be used, if there is much inflammation, but it should not be forgotten that the lead salts turn black in the presence of gases containing sulphur. Bismuth subnitrate may be used according to the following formula:

R.—Bismuth subnitrate	20 grains.
Glycerin	1 drachm.
Rose-water	1 ounce.—M.

Or, the bismuth may be replaced by the same amount of zinc oxide.

In the internal treatment we must be guided by the condition of the patient. Beer and alcoholic drinks should be avoided, and the patient should be kept upon a laxative regimen. The administration of magnesia, in the form of purgative waters, and sulphur, has an excellent effect. In some a change of diet alone is sufficient to cure the acne. If anæmia or other diseased conditions exist, they must be treated on general principles.

Treatment of Foreign Bodies in the Larynx and Trachea.—In a recent monograph upon foreign bodies in the air-passages, by DR. MOURE, of Paris, the following advice is given: Do not use emetics; they do more harm than good, favoring deeper penetration of the body, impaction in the larynx, and sudden suffocation. Hard and heavy bodies may often be displaced by inversion, especially under chloroform, which relaxes glottic spasm. No attempts at removal should be blindly made with forceps; the gravest consequences often follow such procedures. If it is decided to open the larynx, tracheotomy should be previously done. If the body is situated in the trachea or bronchi, deep tracheotomy is necessary, proceeding

slowly and exposing a large part of the trachea. If the object cannot be extracted during the operation, the tracheal wound should be left open and subsequently attempts at spontaneous expulsion be excited, or the patient be inverted.—*Journal of Laryngology and Rhinology*, February, 1890.

Antiseptic Tooth Wash.—The following prescription for an antiseptic mouth wash is quoted in the *Therapeutische Monatshefte*, February, 1890:

R.—Saccharin	. . . .	15 grains.
Sodium bicarbonate	. . .	8 "
Alcohol	. . . . .	3 ounces.
Oil of peppermint	. . .	2 drops.—M.

One teaspoonful in a small glass of water.

The Dose of Antifebrin.—In a paper upon antifebrin (*Prager medicinische Wochenschrift*, No. 48, 1889) Dr. Stein writes that though he uses antifebrin as an antipyretic frequently, he has seen in aged and weak persons doses of eight grains produce disagreeable symptoms of cerebral excitation and even hallucinations. He advises with such patients a beginning dose of one and one-half grains.—*Schmidt's Jahrbücher*, January, 1890.

Antiseptic Treatment of Gastro-enteritis.—A writer in the *Revue Générale de Clinique et de Thérapeutique*, January 23, 1890, advises creolin in the treatment of gastro-enteritis, and prescribes it as follows:

R.—Creolin	. . . .	8 minims.
Pulverized sugar	. . .	75 grains.

Mix, and divide into ten powders, one of which may be given every two or three hours.
Or,

R.—Creolin	. . . .	1 to 2 drops.
Syrup	. . . . .	1 ounce.
Peppermint water	. .	2 ounces.—M.

. Of this a teaspoonful may be given every one or two hours.

Asepsis of the lower bowel may be secured by enemata of one ounce of sodium benzoate in one quart of water; boric acid one to five drachms, sodium salicylate in the same quantities, or resorcin seven grains in a quart of water. Enemata of equal parts of lime-water and distilled water may be used for the same purpose.

The Resuscitation of Asphyxiated Infants.—Dr. Alexander Duke practises the following method of resuscitating asphyxiated infants whose hearts have not ceased to beat:

If the cord is pulsating strongly, he does not cut it at once, but waits for a few minutes, until the pulsation has almost entirely ceased. He then raises the flaccid body of the child, and, turning it face downward, supports the chest with his left hand, and at intervals of five seconds compresses the thorax with the same hand. With the right hand he carefully wipes all mucus out of the mouth and throat of the child, which process is assisted by the position of the infant. If cardiac action becomes weaker, the child is plunged into a large basin of hot water, at the same time rubbing the back and chest vigorously. The friction over the spine is particularly serviceable as a respiratory stimulant. In a few instances he has found it of advantage to suspend the child by the legs, with the back close to a fire.—*London Medical Recorder*, January, 1890.

The Treatment of Sciatica.—Dr. R. M. Simon writes in the *Birmingham Medical Review* that it is essential in every case of sciatica to order absolute rest of the limb. Most cases, if treated thus and with the addition of hot poultices over the affected nerve, will soon recover. In the gouty diathesis it is advisable to prescribe saline purgatives with potassium iodide and antifebrin. Hypodermic injections of morphine or cocaine will give temporary relief, but are not curative. Galvanism may be used while the pain exists, and the best method is that of Stevenson, who applies a positive pole of metal covered with wet chamois skin, and gently passes a carbon disk negative electrode up and down over the course of the sciatic nerve.

It is not unreasonable to suppose that much of the acute pain of sciatica is due to the pressure of increased fluid within the nerve-sheath, and this hypothesis offers an explanation of the good results which often follow acupuncture, leeching, or massage.

Nerve-stretching should be employed only as a *dernier ressort*.—*Medical Chronicle*, January, 1890.

The Parenchymatous Injection of Creasote in Phthisis.—Dr. Andresen, of Jalta, reports his results in the treatment of phthisis by the parenchymatous injection of creasote (*Internationale klinische Rundschau*, February 9, 1890). The injections, sixty in all, were made upon six patients in an advanced stage of the disease. In two patients the injections were immediately followed by slight hæmoptysis, which, however, soon ceased without special treatment. No influence on the fever could be detected in these cases. In one case the cough always became worse for a few hours after the injections. In another case the cough ceased for several hours after injection, then dyspnœa appeared, and the cough became more severe. In a fifth case night-sweats, which had been profuse, were checked for two days. This was observed in this patient on three occasions. A sixth patient suffered from very violent cough and high fever, and there were cavities in each lung. Here the first four injections caused a positive improvement in the symptoms, but later the treatment was without effect.

In Andresen's cases injection into cavities caused an immediate spasmodic cough, burning in the throat, and a strong odor of creasote in the breath, symptoms which were very distressing to some patients. The operation causes but little pain, particularly if practised on the back. Anteriorly in the second intercostal space it causes slight pain lasting a few hours. The amount of creasote used at each injection is not made apparent by the author.

Cocaine Anæsthesia in Litholapaxy.—Freudenberg employs cocaine in large amounts as an anæsthetic in litholapaxy. At first he used fifteen grains for an operation, but found it insufficient, and now uses much larger quantities. In but one of his cases was cocaine intoxication observed. The procedure is carried out as follows: The bladder is first thoroughly irrigated with a boric acid

solution. Then about six drachms of a six, eight, or ten per cent. solution of cocaine is injected directly into the bladder through a soft catheter. The catheter is then partly withdrawn, and an equal amount of the solution is injected through the prostatic urethra into the bladder. Following this the catheter is still further withdrawn, until the eye is in the anterior urethra, which is filled with about one drachm of the solution, the meatus being closed with the fingers. In six or eight minutes the bladder is distended with about five ounces of boric acid solution, and the operation begun.—*Centralblatt für Chirurgie*, February 8, 1890.

The Treatment of Acute Coryza.—DR. C. H. STOWELL advises the following treatment for ordinary acute colds: If the patient is seen early, he should at once have a hot foot-bath and a bowl of hot lemonade. He should then be put to bed and covered with blankets until copious perspiration is produced. If seen at a later stage, the tincture of aconite should be given in half-drop doses for a few hours or until its physiological action is apparent. If the discharge from the nose is thin, or if the throat is involved, small and frequent doses of the tincture of belladonna will give marked relief. A brisk cathartic is often indicated, and generally desirable. Associated with this general treatment in the early stage, the nasal cavities should be sprayed with the following solution:

R.—Cocaine hydrochlorate . 4½ grains.
Antipyrin . . . . 18 "
Sodium bicarbonate . . 5 "
Water . . . . 1 ounce.—M.

The spray should be repeated as often as the nares become occluded. If nasal symptoms remain after twenty-four or thirty-six hours, it is better to substitute a spray with an oil for a base, thus:

R.—Cocaine hydrochlorate . 9 grains.
Water . . . . ½ drachm.
Dissolve, and add:
Fluid cosmoline . . . 1 ounce.
Oil of eucalyptus . . . 6 drops.
Oil of gaultheria . . 3 "

This spray may be used morning and night until the acute catarrhal symptoms have disappeared. The following powder may be used in place of either of the above solutions:

R.—Sodium bicarbonate . . 2 grains.
Magnesium carbonate . 3 "
Menthol . . . . 1 grain.
Cocaine hydrochlorate . 4 grains.
Milk sugar . . . . 1½ drachms.—M.

To be used as a snuff.—*New York Medical Journal*, March 1, 1890.

Balanitis from Applications of Calomel.—M. CORDIER calls attention to a fact which has long since been known, that when tincture of iodine, or iodine ointment, is applied to a surface which has previously been rubbed with mercurial ointment, a severe irritation is set up; this is so severe as to produce vesication at times, and the effects will be observed even if the mercurial inunction has been made some days previously. This explains, partially, the origin of the new variety of balanitis, to which he calls attention in the *Lyon Médical*. It is observed in individuals who, while taking iodide of potassium, make applications of calomel to the glans and prepuce. A severe balanitis generally results. It is very probable that vulvitis, in women, is also often provoked by the same means, so that whenever external applications to the genitalia of men or women are about to be ordered, care should be taken to ascertain whether they are taking iodide of potassium or not. If the former is the case, calomel should be avoided as a dressing. M. Cordier claims that the circumstances alluded to above are a much more frequent case of balanitis than is generally supposed.—*St. Louis Medical and Surgical Journal*, March, 1890.

The Treatment of Eczema in Children.—According to SAALFELD (*Archiv für Kinderheilkunde*), eczema intertrigo about the genital and anal region is especially frequent in fat children, and is usually associated with digestive disturbances demanding the regulation of the diet before anything else. Locally the most grateful and healing application is composed of equal parts of a five-per-cent. solution of boric acid and lead-water applied on pieces of muslin or linen, and renewed every time the diapers are changed. The acute inflammation usually ceases at the end of the second day, when a five-per-cent. ointment of boric acid in vaseline should be substituted for the lotion, painted on with a brush and then covered with the ointment spread on a cloth. If there is much moisture present, the parts should be powdered with talc or equal parts of talc and zinc oxide, and covered with cotton dusted full of the powder. The diapers should be changed frequently, and the old powder, if wet and caked, removed before new powder is applied. In fat children with eczema of the head the supply of fat in the food must be lessened, the frequency of nursing being reduced. If constipation is present, small doses of calomel may be given. Locally all crusts are to be removed by soaking in oil and then removing with soap and water. If much exudation is present, Lassar's paste, with boric acid five per cent., or the benzoated oxide of zinc ointment, may be used. If there is not much exudation, apply a simple five or ten-per-cent. boric-acid ointment. In the squamous stage an ointment of fifteen grains of white precipitate, sixty-five grains of balsam of Peru, and an ounce of zinc oxide ointment will soon complete the cure. The skull-cap of linen is a necessary adjunct to this treatment, and it is well to bind up the hands to prevent scratching. In general eczemas of strumous children either phosphorus or arsenic in cod-liver oil must be administered. Water must be kept away from all eczematous skins.—*New York Medical Journal*, March 8, 1890.

Prescription for Eczema of the Anus and Scrotum.—According to the *Journal de Médecine de Paris* the following is a favorite prescription of Unna for obstinate eczema of the scrotum and anus:

R.—Linseed oil, Lime water, Zinc oxide } of each . 6 drachms.
Iodoform . . . . 1 to 2 " —M.

INTRA-TRACHEAL INJECTIONS OF CREASOTE OIL IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

FROM a theoretical point of view, the discovery of the cause of a disease is the first step toward its specific treatment; but, practically, this is far from being the case. The causes of the very few diseases for which we have specifics have been ascertained long after the latter had been universally employed. Such well-known facts might have moderated the therapeutic expectations that were raised by Koch's discovery of the tubercle bacillus, and doubtless did so in the minds of many thoughtful men who had felt the irony of the maxim: *Sublata causa tollitur effectus*. The search for specifics, however, is still pursued; and the failure of one investigator seems only to incite another to greater and more daring activity. The latest example of this tendency is found in the treatment of pulmonary tuberculosis by intra-tracheal injections, as pursued by DOR, of Lyons, and described in the *Revue de Médecine*, Nos. 10, 1889, and 2, 1890. This method is a modification of that employed by Bechag in the treatment of laryngeal phthisis. The latter, by means of a specially constructed syringe, injected mentholated oil into the larynx, whereas Dor, after slightly altering the instrument, injects creasote oil into the trachea, with the object of causing it to penetrate into the lung parenchyma. That this object may be thus accomplished is proved by experiments on animals, undertaken by Dor before the application of the treatment to man.

If a guinea-pig be killed immediately after the intra-tracheal injection of one cubic centimetre of creasote oil, the latter will be found to have reached the smaller bronchi, and after the lapse of from twelve to twenty-four hours numerous alveoli will be filled with the medicament, which may be found in the pulmonary parenchyma during the period of fifteen days.

In view of the tardiness with which creasote oil disappears from the lung tissue, Dor experimented with two other vehicles for creasote—vaseline and glycerin—but found them both inferior to olive oil, the former giving rise to numerous hæmorrhagic extravasations, and the latter causing intense dyspnœa, marked symptoms of asphyxia, and, in some instances, hæmoptysis.

Dor's solution is composed of five grammes of pure creasote to one hundred grammes of olive oil, sterilized by boiling, and the quantity injected varies from 0.50 to 2 cubic centimetres.

The immediate effect of the injection varies with the individual susceptibility, from paroxysms of cough to well-marked laryngeal spasm. In one instance Dor performed intubation after the injection, although he says the demand for it was not urgent. Very soon after the injection all disagreeable sensations disappear, and a tolerance for them is soon established; so much so that some patients are said to continue talking until the moment of injection, resuming the thread of their discourse, or completing an interrupted sentence, immediately thereafter. One patient, after leaving the hospital, administered the injections to himself.

Dor characterizes the injection of medicinal substances into the lung tissue by puncturing the subclavicular tissues or the trachea as a barbarous proceeding, and in this we are inclined to agree with him. The criticism to which all intra-pulmonary injections are exposed is the absence of certainty as to their direction. With Dor's method there can be little doubt that the injected material must invade and occlude a certain number of sound alveoli, every one of which is needed for the function of the crippled lung. He endeavors, it is true, to direct the injection toward one side or the other by advising a left lateral decubitus when the left lung is affected, and *vice versa*, and no doubt with a certain amount of success.

This method of treatment has been followed systematically in twenty cases which, so far as their progress is concerned, may be divided into three classes: 1. Those exhibiting marked improvement. 2. Those whose improvement was slight. 3. Those whose condition remained the same or grew worse.

The first class numbered seven and the improvement was manifested principally by diminution or cessation of cough, and increase in weight. In these cases, with one exception, the treatment lasted more than fifty days, from three to ten grammes of pure creasote in from sixty to two hundred cubic centimetres of oil having been injected.

The second class numbered eight, and was characterized by diminution of the expectoration, slight increase in weight and reappearance of appetite. As a rule the cough persisted. The treatment in these cases lasted from seventeen to sixty-eight days.

Of the remaining five cases, the treatment was imperfectly carried out in three, and the remaining two were complicated with pleurisy.

Dor advises that the treatment be continued for at least one month, during which two cubic centimetres of creasote oil are injected twice daily. In cases with large vomicæ, he recommends the employment of a more powerful antiseptic than creasote, and suggests a solution of camphorated naphthol.

The results reported by Dor, although based upon a small number of cases, seem to warrant a further trial of this mode of treatment. The chief obstacle in its way is that it calls for a degree of manual skill possessed by few, and this fact may be used either as an argument for the reference of phthisical cases to the throat specialist or the cultivation of the use of the laryngoscope by the general practitioner.

REVIEWS.

A Manual of Organic Materia Medica. By John Maisch, Ph.M., Phar.D. Fourth edition. 12mo., pp. 539. Two hundred and fifty-nine illustrations. Philadelphia: Lea Brothers & Co., 1890.

A work which, like the one before us, has passed through four editions in seven years, is too well known to require more than a passing notice. The scope of the work "embraces the drugs of animal and vegetable origin recognized by the Pharmacopœias of the United States and Great Britain, supplemented by important non-officinal drugs." The subject is one in which a good classification is almost as important as accurate description, and each of these requirements is so well attained by Professor Maisch that materia medica is divested of much of its proverbial "dryness."

The present edition differs from the preceding chiefly in the addition of a list of drugs arranged according to origin—an arrangement which seemed to be particularly appropriate at the present time, in view of the approaching revision of the United States Pharmacopœia.

Not the least important feature of the volume, is the number and excellence of the illustrations, which are remarkable for clearness and perfect execution.

The book is warmly recommended to students as a text-book, and to physicians and pharmacists as a work of reference.

The Physician's Leisure Library. Education and Culture as Correlated to Health and Diseases of Women. By A. J. C. Skene. 12mo., pp. 127. Detroit: George S. Davis, 1889.

Just at this time, when so much interest is shown in the subject in which this book deals, it is not unnatural that so pushing a publisher should put upon the market a book written by one whose long experience should certainly qualify him to act as a judge concerning the questions of which he writes.

The book before us is written in an easy conversational style, and is not loaded down by a large amount of stupid statistics and figures, devoted to the proving of the statements of the author, and, at the same time, a sufficiently scientific tone is maintained to prevent the text from becoming too dogmatic. Through an error on the part of the printer, we notice that on the cover the author's name is placed as "J. A. C. Skene," but on the front page as "A. J. C. Skene," the latter, of course, being correct.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Section on Pediatrics.

Stated Meeting, February 13, 1889.

L. Emmett Holt, M.D., in the Chair.

Dr. A. Seibert presented an improved sterilizer and set of nursing-bottles, and read a paper entitled

A REFORM IN ARTIFICIAL FEEDING OF INFANTS.

He said, at the outset, that all food entering the body above the requirements for nutrition, was a hinderance to digestion and a danger to health. It might be stated as a rule, to which the exceptions are few, that children who are artificially fed are over-fed, often very greatly so. It is only very recently that the mind of the medical profession has been turned at all in the direction of the quantity of food required by infants. It has been said by many writers that healthy children fix a proper limit for themselves; that children ought to be fed from the breast or bottle until they have had enough, etc. Hitherto, those who have studied the subject of quantity in infant feeding, have made their calculations according to the age of the child, and have disregarded other conditions. One cause for the continued over-feeding of infants, has been that the ordinary nursing-bottles in use have been much too large, often only a single size being

used during the whole period of infancy, or at least for the first year.

During the last two years, Dr. Seibert has made a very large number of experiments in weighing infants, to see if it were possible to deduce from the weight a rule as to the quantity of food which would be a good guide in practice. From these experiments, covering observations upon over two hundred cases, he has formulated the following rules:

Children of 6–8 pounds require 3 ounces at a time every 2 hours by day, or 8 bottles in the 24 hours.

Children of 9–10 pounds require 4 ounces at a time every 2 hours by day, or 8 bottles in the 24 hours.

Children of 11–14 pounds require 5 ounces at a time every 2 hours by day, or 7 bottles in the 24 hours.

Children of 15–16 pounds require 6 ounces at a time every 2 hours by day, or 7 bottles in the 24 hours.

Children of 17–18 pounds require 7 ounces at a time every 2 hours by day, or 6 bottles in the 24 hours.

Children of 19–20 pounds require 8 ounces at a time every 2 hours by day, or 6 bottles in the 24 hours.

The apparatus devised by Dr. Seibert consists of a tray, capable of holding eight bottles, and which may be placed in any ordinary cooking pot or steamer. The bottles are made in six sizes, the smallest holding three ounces, and the largest eight ounces. The bottles are somewhat oval in form, with a small, flat bottom, without any neck, and with no angles, so that they can be cleaned with the least possible difficulty. They are closed during steaming by rubber corks which have a furrow in the lower third, to allow the steam to escape during the steaming process; at this time the cork is pushed only partly into the bottle. When the steaming process is completed, these corks are pressed down and the bottles made air-tight. The tray is made of tin, and one size can be adapted to hold the different sizes of bottles. Two cupfuls of water are put into an ordinary pot or steaming apparatus, and the tray set in. Dr. Seibert advises the steaming to be continued for thirty minutes in the cool season, and forty-five minutes during warm weather. The apparatus, including the tray, eight bottles with stoppers and rubber nipples, has been manufactured so that it is retailed for one dollar. Upon each bottle is stamped in the glass the frequency of feeding, and the weight of the child for which it is advised. For example, upon the eight-ounce bottle, "for a child of 18–20 pounds, feed every three hours." Upon the smaller bottles is a mark indicating the level to which the bottle should be filled with milk, and the remainder with some diluent, either barley, gruel, oat-meal gruel, etc. The advantage of having the bottles of different sizes, and of such a capacity that they are to be filled for each meal, is evident. There is no temptation on the part of the mother to put two or three meals in one bottle, and she has always measured for her the proper quantity for a single feeding. Dr. Seibert stated that this apparatus was intended especially to meet the wants of the poor and ignorant classes, among which the most serious consequences of over-feeding were seen, often little or no attention being given to the quantity of food administered. After two years' experience with this method of feeding, being guided by the weight, and not the age of the child, in ordering the quantity of food, Dr. Seibert is firmly convinced that the principle is correct. It is to be applied not only to healthy, but also to convalescent children. The amount of work done by different infants is practically the same, consequently the amount of food required will depend upon the size of the body and the amount of tissue to be nourished.

Dr. J. Lewis Smith opened the discussion upon Dr. Seibert's paper. He thoroughly appreciated the dangers from over-feeding, and regarded this evil as perhaps the most potent cause of gastro-intestinal diseases. He was not quite convinced as yet, that our former method of being guided in the quantity used by the age of the child, was altogether wrong. It was certainly true that there were many cases in which, were we guided by the weight alone, we would fall into error. For example, many children suffering from rickets have large bodies with flabby tissues, often exceeding in weight, by three or four pounds, healthy children of the same age. Manifestly, in this condition, it would be wrong to increase the amount of food according to the child's weight. In convalescing from acute diseases, when a child had been greatly wasted, he thought it would not be a good guide to follow only the weight of the child. Its appetite, its power of digestion, and its general well-being, are also to be taken into consideration. Dr. Smith presented a table quite similar to that published by Dr. Rotch in Keating's *Cyclopædia*, which he had deduced from some experiments made in two institutions to ascertain the actual amount of food taken by nursing infants. Dr. Smith was not prepared to give up the old method of deciding how much a baby should be fed.

Dr. J. E. Winters thought that Dr. Seibert had overstated the frequency of over-feeding among artificially fed children. He could point to a large number of children brought up artificially, in which this had not been the case. He said it was a great mistake to say that the amount of work done by two infants of the same age was the same. One infant would be in almost continuous motion, and its muscles in a state of frequent contraction. Another would be quiet, and sleeping most of the time, getting very little exercise. He thought as much difference was seen in infants, in the amount of muscular work performed, as between an ordinary day-laborer and a bookkeeper. He was inclined to agree with Dr. Smith, that it was only exceptionally true that the weight was a correct guide to the amount of food required. He thought we would be worse off than at present if such a method were generally adopted. There was no more reason why two infants of the same weight required the same amount of food than two adults. It certainly was not true that a man of 225 pounds required double the food of a man weighing 112 pounds.

Dr. W. P. Northrup believed that Dr. Seibert's work was a step in the right direction. He thought the cases stated by both Drs. Winters and Smith were exceptional ones. What Dr. Seibert was aiming at was a general rule for practice, and he believed the one which had been presented would prove useful. Certainly, in the matter of bottles, the apparatus presented was a great improvement upon any now in the market. In regard to sterilizing milk, he did not think that boiling for thirty minutes was sufficient to destroy all the germs present. It might possibly be sufficient to destroy the ordinary germs which sour milk, but was not enough for the bacillus tuberculosis. It ought to be understood by all

that steam was much more effective as a sterilizing agent than hot water, the water bath being but a very poor substitute for steam. This was often used with the idea that it was ample.

DR. DORNING believed that all the circumstances surrounding the child should be taken into consideration in prescribing its quantity of food. If too much was given, vomiting almost always took place. The quality of the food, as much as the quantity, should be taken into consideration.

DR. SEIBERT thought that the regurgitation of food, or vomiting, was not a good guide as to the fact of over-feeding. A large number of these children never vomited, but suffered more or less from intestinal indigestion and dyspepsia. He had found the method advocated to be most beneficial in cases of convalescence from acute diseases, where, week by week, or day by day, if necessary, according to the increase in weight of the child, the food should be steadily increased.

The CHAIRMAN stated that he thought Dr. Seibert was in error in stating that the weight of the child and the capacity of the stomach bore a constant relation to each other. For the past two years he had been measuring, at autopsy, the stomachs of all infants, these being very carefully distended under hydrostatic pressure until all the folds of the mucous membrane were obliterated, but not beyond this point. These investigations showed a pretty constant relation between the age of the child and the stomach capacity. Thus, beginning with one ounce at birth, it increased on the average nearly one ounce a month for the first six months, and one-half an ounce a month for the second six months of life.

DR. E. L. PARTRIDGE reported a case of

SUDDEN DEATH IN AN INFANT FROM AN UNUSUAL CAUSE.

A stout, well-nourished infant, four months old, in care of a wet-nurse, was put in its crib after nursing, and was found dead half an hour later. The child was reported to have been shaken slightly by the nurse before putting it down. No other evidence of violence could be discovered. At the autopsy the trachea, larynx, and larger bronchi were found to contain a considerable quantity of milk. There was also milk in the œsophagus and pharynx. It was Dr. Partridge's opinion that death had been caused by the entrance of milk into the air-passages.

DR. WINTERS suggested the probability that the child had also been drugged by the wet-nurse, this practice being so exceedingly common with this class of women.

CORRESPONDENCE.

PARIS.

Diabetes. Hypnotism in Obstetrics. Ambulatory Automatism. Suture of the Patella.

To the Editor of THE MEDICAL NEWS,

SIR: PROFESSOR LÉPINE, of the Faculty of Lyon, has confirmed the existence of pancreatic diabetes, which has been clinically demonstrated by Dr. Lancereaux. Dr. Lépine has demonstrated that the complete removal of the pancreas of a dog is followed by a more or less pronounced diabetes. This diabetes, however, does not occur if the slightest portion of pancreas is left, even if the excretory duct has been removed. This the author explains in two ways:

The first theory is that in the normal state part of the pancreatic ferment is re-absorbed and contributes to the destruction of the glucose which may be present.

In fact, if a pancreas is cut to pieces and then placed in a solution of glucose, we find, after a certain lapse of time, that the quantity of sugar has diminished.

The second hypothesis is based on the fact that with diastase starch is transformed into maltose, then into glucose, and that the same occurs when the pancreatic juice is brought in contact with glycogen.

The transformation of glycogen into glucose is, then, a complicated process, which necessitates the intervention of the pancreatic ferment. In the normal state, this ferment is re-absorbed by the pancreatic veins, and passes to the liver through the portal vein. If the hepatic sugar increases or diminishes, it is no longer glucose, but a foreign sugar which is eliminated by the kidney, instead of being used for the purpose of combustion. In either case the pancreatic diabetes would be the result of the presence of too small a quantity of ferment, and a diabetic state would result in consequence of the relative deficiency of ferment, as compared to the quantity of hydrocarbon to be destroyed.

To prove the diminution of the quantity of ferment in the blood, the following experiment has been made. The entire arterial blood of two dogs is separately collected, both dogs having been fasting for sixty hours; but one is normal, while in the other the pancreas has been completely removed. The quantity of sugar of these two specimens of blood diminishes; but while, at the end of fifteen hours, the diminution has amounted to thirty-nine per cent. in that of the healthy animal, it was only eight per cent. in the other.

Again, if we add to each blood, as soon as it is withdrawn, an equal quantity of starch, we find that six times less sugar is produced in the blood of the mutilated dog than in that of the normal animal; which shows, of course, that the latter's blood is much more rich in ferment.

Drs. Arthaud and Butte have also undertaken a series of experiments on this subject, to determine the reason that the total extirpation of the pancreas brings on glycosuria, as was first indicated by Drs. Minkowski and von Mering.

The first hypothesis previously advanced is, that if the pancreas is removed, the elimination of the pancreatic diastase which is usually contained in the blood fails to take place, it is retained in the organism, and augments the transformation of the reserve of glycogen. To control this fact, Arthaud and Butte have made injections of either vegetable diastase or macerated pancreas, but have never observed glycosuria to follow; hence one cannot admit the accumulation in the organism of a diastase capable of producing glucose.

These authors also reject the opinion of Lépine, who says that the pancreas yields to the blood a ferment capable of destroying the sugar in the economy; if the pancreas is removed, the ferment which destroys the sugar disappears, and we have glycosuria. In an experiment, during which they ligated almost all the veins of the pancreas in a dog, the urine was not found to contain an increased amount of sugar, which phenomenon

should have been observed if the pancreas excreted, by its veins, a ferment capable of destroying the sugar in the organism.

MM. Arthaud and Butte, having observed in their experiments that in every case of glycosuria there was a constant lesion—namely, a dilatation of the hepatic arterial system—thought that the glycosuria might be due to an increase of the hepatic circulation, on account of the suppression of an important collateral circulation. To establish this fact, they ligated the different branches of the cœliac axis of a dog, excepting the terminal branch of the hepatic artery; the animal died at the end of three months, and sugar was always found in his urine. The naked-eye appearance of the pancreas showed no alteration, which is not astonishing, as the arterial circulation had been reëstablished in this gland by the mesenteric artery which had not been ligated.

Dr. de Grandchamps has used hypnotism in one of his hospital obstetric cases, with most gratifying result. The patient was a girl, seventeen years of age, with no signs of hysteria. She presented herself at the hospital in the fifth month of her pregnancy. Dr. de Grandchamps thought of preparing the patient beforehand, so that he might fully hypnotize her when labor came on. She was easily hypnotized at the first *séance*, and Dr. de Grandchamps repeated the hypnotization two or three times every week, with great benefit to the patient, who was very anæmic. She rapidly recovered her health, her cheeks became red, and her appetite and sleep perfect. Finally, labor began; the dilatation of the neck was complete. As in every labor, the contractions were most painful to the patient, as indicated by her loud cries. In the quiet moment following a contraction, Dr. de Grandchamps rapidly hypnotized the patient, and suggested to her to bear down when the contractions came on, but that she would feel no more pain. From this moment the contractions became very strong, but the patient did not utter the least cry or sound. After awhile, the doctor, desiring to increase the rapidity of the labor and to regulate the contractions, commanded the patient to bear down every minute. The order was obeyed, and every minute a contraction took place, followed by a period of repose. This methodical bearing-down soon brought the head to the vulva, and, as she was a primipara, fearing a too hasty expulsion, the order was given her to bear down no longer. From this moment the movements stopped, and the head and trunk came out slowly, without active intervention on her part. A quarter of an hour after her delivery this young woman awakened, and could not believe that she had been delivered.

A very interesting case of ambulatatory automatism, first described by Charcot, has occurred in the practice of Professor Prourt.

The patient is a man, thirty-three years of age, son of a nervous and inebriate father, mother also nervous; he has a brother deficient in intellect. The patient, however, is very intelligent, well educated, and one of the lawyers of Paris. He presents unmistakable signs of hysteria, and he can be very easily hypnotized. Professor Luys, who has treated him, found that a loud noise would immediately throw him into this hypnotic state. On one occasion he fell into the hypnotic state in the street from glancing at a mirror. On another occasion, while pleading in a court of law, the president looking at him, he suddenly fell asleep, stopped his discourse, and was only able to resume it when a friend had awakened him.

At other times his memory is completely lost; he entirely forgets his past existence and his own personality, but during this state a sort of new life begins for him, and a new memory and individuality are established. He walks, travels on railroads, makes social visits, and, finally, suddenly returns to his normal state, forgetting all that has taken place.

After a violent discussion on the 23d of September, he lost his memory until the middle of October; he does not know what he has done, how he has lived, where he has been. In the middle of October he found himself in a village at some distance from Paris, and then came back to his normal state. During that time, he discovered later, he had contracted debts for over one hundred dollars; and, having stolen money, he was condemned for theft by a court of law.

This is a clear case of ambulatory automatism, and shows:

First, a suspension in the continuity of consciousness although the individual is able to conduct himself as in ordinary life and without attracting attention.

Second, if there exists a discontinuity between the phenomena of consciousness of the secondary condition and those of normal life, there is, on the contrary, a continuity of consciousness between the periods of this secondary condition — for instance, this patient in his normal state ignores what he has done during the periods of ambulatory automatism; but if he is placed in the hypnotic state, he enters into this secondary condition, and is then enabled to recollect everything that occurred while previously in that condition. When in the normal state he is unable to recollect what he did between September 23d and October 15th; when hypnotized, he tells the details of his life during that period.

At a recent meeting of the Academy of Medicine, Dr. Lucas Championnière read an interesting communication on the treatment of fracture of the patella by opening the knee-joint and wiring the fragments. The observations included fourteen cases of patellar fractures, four being old fractures, and nine recent, and in one case the patella was intentionally ruptured on account of vicious union. The operations for the recent fractures were made between the first and twelfth day; two were made less than twenty-four hours after the fracture, and one less than twelve hours after. Rapid intervention is always advisable. The articulation is well cleansed, and, after having removed splinters of bone, the patella is sutured by means of two wires passed through the middle. The parts surrounding the articulation are drained with care, as there is always more or less effusion. Finally, he places the limb in a splint for eight days, after having dressed the wound. The limb is not kept completely immovable. It is only between twenty and twenty-five days after the operation that the patient is allowed to walk, and it is surprising to note how rapidly he is enabled to do so. In recent fractures osseous union is positive, as it is quite impossible to find an interval between the fragments, and one can feel the wires through the skin.

The patella becomes very strong, and when the patient is cured no appreciable difference will be found

between the diseased and healthy limb, and this result is permanent. No other treatment will allow a patient to walk perfectly within six weeks or two months.

When the ordinary methods of treatment have been used previous to the operative intervention the results are not so favorable; out of five cases, a perfect union was obtained in two, but in three other cases the separation between the fragments was not completely obliterated, though the silver wires were retained in position.

This operation must, of course, be done under the strictest antiseptic precautions, and strong silver wire should be employed. Dr. Championnière especially insists on the importance of not rendering the articulation immovable after the operation.

VIENNA.

To the Editor of THE MEDICAL NEWS,

SIR: The treatment of tabes dorsalis has attracted a good deal of attention here lately, following the French experiments of suspending the patient and trying to influence the sclerosis by stretching the spinal cord. No one knows how any effect can be produced, but it is certain that some slight improvement takes place, probably because the hopes of the patient are revived by complicated machinery. It has been tried here, but, just as pathologists predicted, with no other results. Hardly a week passes without our seeing a new case of the disease in Nothnagel's wards. Erb has been studying its etiology, and from an experience in several hundred cases, has proven that ninety per cent. of the afflicted are syphilitic. In Nothnagel's wards the same proportion holds, and, judging from this, a very close etiological connection seems to exist between syphilis and tabes. This is further borne out by the experience that potassium iodide and mercury are often beneficial if given early in this disease.

Professor Esmarch, of Kiel, has recently published a new theory which has already received support from such men as Czerny and Albert. According to Esmarch, there has been so much syphilis among the lower classes in Europe that has not been thoroughly treated, that by heredity nearly all the population have some of the virus in their blood, but in such attenuation that it causes few acute symptoms. Now, in a very large number of tumors that resemble sarcoma almost exactly, microscopic examination fails to show the characteristic cells of this neoplasm, but does give the appearances peculiar to gummata. In most cases where this occurred in Esmarch's extensive practice, he declined to remove the growth by operation, but used inunctions of mercury and general anti-syphilitic treatment. To his great surprise, he was remarkably successful in this method. He first used the method only in cases where an operation was impossible; he then applied it to less advanced cases, and gradually formulated his ideas until now he says that many cases of apparent sarcomata are really gummata, and curable by antisyphilitic treatment. In sarcoma, when operation is no longer practicable, Albert uses deep injections into the tumor of Fowler's solution. Beginning with one drop, he gradually increases to thirty drops daily, and then gradually diminishes the dose. For an hour or two after the deep injection the patient has severe chills and high temperature, an intense itching in the skin, and signs of collapse; but these symptoms soon disappear, and are followed by a long period of perfect ease. I have seen the size of the growths diminishing decidedly with this treatment, but, of course, it is only a palliative measure.

One of the most remarkable cases of heart malformation on record was shown at Nothnagel's clinic lately. A boy of eight years had been in the hospital for several months, with a diagnosis of "pulmonary stenosis and communication between right and left ventricles." The boy died from pulmonary hæmorrhage, and at the post-mortem was found the following: The left auricle opened normally into the left ventricle; the right auricle also opened into the left ventricle, but there was no communication between the right auricle and right ventricle; from the left ventricle the mixed blood from both auricles was sent to the aorta and also through an opening into the right ventricle, and thence into the pulmonary artery. The left ventricle was large, its walls hypertrophied, and it had four valves: one from each auricle, one to the aorta, and one to the right ventricle. The right ventricle was very small, and seemed to be a mere antechamber to the pulmonary artery; it had no communication with the right auricle. There was stenosis at the pulmonary artery. Owing to the mixed character of the blood, the boy always looked intensely cyanotic; his skin was cold and clammy, and his temperature always a degree or two below normal.

The excruciating pains of tic douloureux have given rise to great variety of treatment, illustrating the adage that "the more remedies the less cure." Fränkel has now a new plan which he claims is superior to all others. He gives a hypodermic injection of cocaine in the affected place, and then applies the strongest current of faradic electricity the patient can bear, placing one pole at the foramen of exit, and the other on the course of the nerve about half an inch distant. Without the cocaine the current could not be applied strong enough. There have been excellent results in the cases we have seen, and the method certainly deserves further trial.

Cirrhosis of the liver is a common trouble in Austria, and innumerable remedies have been used for its relief. In the University clinics they now prefer calomel given by the Russian method—*i. e.*, one-half to one grain daily. It promotes diuresis, and by this means probably reduces the ascites. They also give it in cases of hepatic enlargement from passive hyperæmia, where it does excellent service. There is an evident current in professional opinion here that is limiting the number of medicines ordinarily used. It is rare to see a prescription from the professors here that contains more than two or three ingredients. Simplicity in therapeutics is the password, and the day of the "shotgun prescription" is evidently past. The great University here has but one Professor of Materia Medica, while all the other departments have numerous representatives. The study seems to tend toward pathology more than in any other direction. From a knowledge of the changes produced by disease they are striving to discover how to prevent and how to cure. Every case that dies in the hospital is examined most thoroughly post-mortem, and four skilled pathologists attend to this work. Thus there is always proof of correctness or mistake in diagnosis, and the diagnosticians are constantly held to facts, and reminded of their fail-

ures, so that every error is a lesson of great value. It is because of this system that the Vienna clinicians have such a reputation in diagnosis—they never fall into errors without the constant influence of pathology bringing them back to facts.

A few days ago, Dr. Rosthorn, assistant at Professor Chrobak's gynecological clinic, operated on a case of apparent ovarian cyst. Eight weeks before, the woman had been delivered of an eight months' child, normal labor, and had been perfectly well until three weeks previous to the operation. The operation was made in the ordinary way, and the supposed cyst removed. At one portion of it a peculiar cord-like process was attached. Rosthorn examined the other ovary—it was normal—but, while examining it, a small hand slipped out from between the intestines. This was seized, and a full-sized child was removed from the abdomen, and to its umbilicus was attached a cord exactly similar to that found on the cyst. They then looked for the fœtal membranes, and found them very deep and everywhere adherent to the intestines and peritoneum. The child's skin was nearly normal, though slightly macerated. Then the membranous sac was brought up and sewed to the peritoneum, just as the stump is treated in extra-peritoneal amputation of the uterus; the abdominal walls were united, and the sac dusted with salicyl-tannin. The woman rallied, and now, seven days after the operation, is doing very well. The careful examination of the removed cyst showed that the tumor was merely the placenta coiled up where it had been fastened to the left Fallopian tube, and the case now resolves itself as follows: There was an extra-uterine pregnancy, with the fœtus in the left Fallopian tube, and this fœtus was carried beyond term, and died. Throughout the time there were no symptoms from this extra-uterine pregnancy, and an intra-uterine pregnancy went on nearly normally at the same time. It cannot be established, though it is probable, according to the authorities here, that the two children were really twins, and one developed within, the other outside of, the uterus. Thus it stands without a parallel in the history of obstetrics, and the full report by Rosthorn will be looked forward to with great interest.

Bacteriological investigation goes on constantly with undiminished vigor, and at last the subject of malaria seems settled. It is taught here that the plasmodium malariæ is the cause, that it enters the blood, taking up its abode in the red corpuscles, and gradually growing therein. At first it is very small, one-fifth the size of the corpuscle, but as it grows it takes up pigment, which is deposited in small granules in its periphery. It grows until it completely fills the corpuscle, and then it divides into a number of daughter cells that repeat the same process, and at the division the pigment granules are set free in the blood, causing the well-known *melanosis malariæ*. There is very little malaria in Vienna, but Dr. Bamburger, Nothnagel's first assistant, told us that in every case they succeeded in finding the plasmodium. The use of quinine diminishes the number of the organisms very markedly, and in case of cure they can no longer be found. They are also more numerous just before the chill, and immediately afterward are hard to find, for then the division has taken place, and the small cells escape observation far more easily. Golgi, an Italian pathologist, has written an excellent monograph on this subject.

Professor Rosenthal, the author of a work on nervous diseases, died here a few weeks ago, a victim to the influenza. Professor Albert is very ill at the present time, from some throat trouble, and Docent Hochenegg is filling the chair during his chief's absence.

In the last few years there have been twelve Cæsarean sections in Chrobak's clinics; they were all made after the Porro method, and in no case was child or mother lost. In the last thirty cases of uterine fibroids removed by the extra-peritoneal method of amputation there were but three deaths, and the mortality in simple ovariotomy has been reduced to almost *nil*. The most thorough antiseptic precautions are observed here, and to this are attributed these wonderful results.

LONDON.

The Late Sir William Gull; The Study of Infectious Diseases; The Chloroform Commission; The Re-constitution of the University of London.

To the Editor of THE MEDICAL NEWS,

SIR: The death of Sir William Gull has removed from our midst one who has occupied for the past quarter of a century the most prominent place in medicine, though for the last two years, since a slight cerebral attack, he had been unable to engage in practice. Sir William Gull's great reputation and success were earned by most assiduous clinical work in his younger days. For fifteen years he lived practically, if not actually, in Guy's Hospital, and devoted himself entirely to clinical medicine and pathology, and his writings in the well-known annual reports of this hospital are a sufficient proof that he made the most of his opportunities. I have heard regrets that he never wrote a book; but book-makers are not, as a rule, the people who do good original work, but rather those who know how to assimilate the work of others, and Gull's work will undoubtedly live and undergo this process of assimilation. Had it not been for the failure of his health, there can, I think, be little doubt that he would have attained to the highest distinction open to a physician, viz., the presidency of the College of Physicians, when Sir William Jenner retired some two years ago; but, unfortunately for him, his working days were then already over. It is pretty generally believed that had it not been for his incessant care the Prince of Wales would not have pulled through the very severe attack of typhoid fever which imperiled his life about eighteen years ago.

In my last letter I alluded to the steps that were being taken to afford facilities for the study of infectious diseases in London. I am happy to be able to report that the negotiations that were then in progress have been brought to a most successful issue, and the details of the scheme by which the fever hospitals of the Metropolitan Asylums Board were laid before the College of Physicians at the last meeting, and unanimously approved. It will mean, no doubt, a prolongation of the medical student's career, but except on the score of expense, there is nothing to be said against it. At present, the study of these diseases is not compulsory, but, no doubt, many students will not be slow to avail themselves of the much

desired opportunity for becoming familiar with measles, scarlet fever, *et hoc genus omne*, before venturing into practice on their own account, and in a few years it is quite likely that we shall find that a three months' clerkship at a fever hospital is a *sine qua non*.

Dr. Lauder Brunton has returned from his chloroform experiment expedition in India, and has published the results of his investigations in the *Lancet*, and also in a paper read before the Medical Society at its last meeting. He tells us that chloroform and ether act in the same way; that both paralyze the respiratory centre before the heart; that if you push one or the other after the respiratory centre has ceased to act, then you paralyze the heart; and that chloroform is a more potent remedy than ether, and will paralyze the respiratory centre and stop the heart earlier than ether. The chief conclusion is, that death from chloroform is due to asphyxia, and that where deaths occurred under such circumstances, they were due to imperfect observation of the respiration; his advice, therefore, is that more attention should be paid during the administration of chloroform to the condition of respiration.

The vexed question of an attainable medical degree for London students is again being agitated. A Royal Commission sat on the subject, and made certain suggestions to the existing University of London, and the senate of that body in their praiseworthy endeavor to meet the views of the Commissioners have issued a scheme of modifications to overcome the existing difficulties, which are admitted on all sides. There are, of course, many who are discontented with the proposals. Hitherto the University of London has been a university only in name; in fact it has been nothing more than a huge machine for examining men, and it has done its work efficiently enough by the standard which it has set, but its rules have been so exclusive that unless a boy decided, whilst still in his teens, that he would endeavor to obtain the degree, it has been almost impossible for him to do so afterward. The preliminary examination which must be passed has blocked the way, and when a student has begun the real work of his profession, he can but rarely afford the necessary time to begin again and pass a preliminary examination. I confess I do not quite see why we may not have an entirely new teaching university here. The population of London alone is almost as great as that of Ireland, where there are three universities, and it is greater than that of Scotland, where there are four; but at present the minds of all are engaged in endeavoring to mould the existing university into something that will do all that is required. I am doubtful if success will be attained, as there are many interests which at present show no symptoms of conciliation. A conclusion must, however, be arrived at before long, as the Commissioners gave the University only one year to consider whether it would make the needful changes, and not a small part of the year has already elapsed without any definite result having been reached.

NEWS ITEMS.

The Boston City Hospital.—The new out-patient building of the Boston Hospital is now occupied. The Home for Convalescents at Dorchester will next be erected, $30,000 having been appropriated by the Common Council for that purpose. The Hospital also needs a new building for its medical and patients' libraries, with a dining room for the house staff. For this addition $18,000 has been asked.

The Price of Quinine.—Contrary to the expectations of many, the enormous consumption of quinine resulting from the pandemic influenza, has not greatly enhanced the price of the drug. A late London trade circular shows that in Mincing Lane the increase has not been more than a halfpenny per ounce. The offerings of cinchona in the market at each fortnightly auction have been so full and regular that the price of the manufactured article could not be materially advanced.

The Modern American Physique.—Dr. J. B. Hamilton, of the Marine Hospital Service, recently delivered an address before the Georgetown Medical College upon the physical culture of ancient and modern times, in the course of which he is said to have made a generalization to the effect that not one-third part of our American population of the military age could pass the physical examination of the recruit.

Starling Medical College.—The forty-third session of Starling Medical College, Columbus, O., closed with appropriate commencement exercises Thursday evening, March 6th, graduating thirty-nine men. During the past term the attendance was larger than it has been since 1852.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 4 TO MARCH 10, 1890.

KIMBALL, J. P., *Major and Surgeon.*—Is granted leave of absence for twenty days.—Par. 1, *S. O. 25, Department of the Missouri.*

HOFF, J. VAN R., *Captain and Assistant Surgeon.*—Is granted leave of absence for one month.—Par. 1, *S. O. 26, Headquarters Department of the Missouri, Fort Leavenworth, Kansas*, March 5, 1890.

MORRIS, EDWARD R., *First Lieutenant and Assistant Surgeon* (Fort Shaw, Montana).—Is granted leave of absence for one month.—Par. 1, *S. O. 28, Headquarters Department of Dakota, St. Paul, Minnesota*, March 7, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING MARCH 8, 1890.

SCHOFIELD, W. K., *Medical Inspector.*—Ordered for examination preliminary to promotion to Medical Director.

MCMURTRIE, D., *Surgeon.*—Ordered for examination preliminary to promotion to Medical Inspector.

GATES, MANLEY F., *Assistant Surgeon.*—Detached from the Navy Yard, League Island, and ordered to the U. S. S. "Kearsarge."

HARRIS, H. N. T., *Assistant Surgeon.*—Detached from the U. S. S. "Kearsarge," and ordered home.

ORIGINAL LECTURES.

THE PATH OF MOTOR AND SENSORY REINFORCEMENT.

Abstract of a Clinical Lecture delivered at the Infirmary for Nervous Diseases of the Orthopædic Hospital.

BY S. WEIR MITCHELL, M.D.

[Reported by GUY HINSDALE, M.D., Assistant Physician to the Hospital.]

SINCE the discovery, by Dr. Morris J. Lewis and myself, of sensory reinforcements, and our amplification of Jendrássik's discovery of motor reinforcements, I have been on the watch for chances of studying the tracks followed by the impulses aroused by these agencies. Opportunities for useful examinations of the tracks of reinforcements are, of necessity, rare, and, perhaps, some may have been neglected, because neurologists, as yet, have hardly realized the importance of this new means of examining the state of the muscle-reflexes. Moreover, until it is surely made clear as to whether reinforcements are explicable by, or due to, "overflow," or to releases from inhibitory controls, all distinct applicatory explanation becomes difficult. Facts must accumulate, and we must look largely to the laboratory for a solution of much that is yet obscure. Every use, however, has not been made of clinical chances, and I shall, in closing, point out what these are.

The case here presented is a contribution to the symptomatic study of reinforcements and of some minor points in a case of spastic paraplegia, in which both spasm and palsy are perfectly represented. The case seems to me so important that I give it in unusual detail, as follows:

Mrs. C., American, aged thirty-seven. Family history: Her father is living and has chronic rheumatism quite severely; mother living and in good health; all other family history is negative.

Personal history: She was married at the age of twenty-eight; her husband is still alive and has never had syphilis. She began to menstruate at the age of fourteen, but has been irregular, often menstruating at periods of three weeks and in excessive amounts.

She has had but one child, which had to be delivered by instruments at the end of a labor of eighteen hours' duration. This child was weak and puny, and was nursed at the breast until two years old. It has since died at the age of five years. Mrs. C. has had the usual diseases of childhood, and typhoid fever when quite young.

Three years ago she was thrown from a horse, sustaining no special injury, and had no sequence except the soreness consequent upon the fall. She has been occupied by housekeeping duties, and was much out of doors.

On the second right upper incisor there is a very faint blue appearance in the gum. On the opposite side of the lower jaw there is a similar appearance, but still more doubtful. The water-supply of the town in which she lives comes from the mountains and is stored in cisterns. She says there is no lead in any way connected with this water-supply, nor does she know of any means by which lead could have been taken into the system. There was none found in the urine. Her duties bear no relation to her present indisposition. Her habits are all good. The date of her present trouble is indefinite, but, so far as she knows, it was nine and one-half years ago that, in consequence of feeling awkward as to motion, it became unusually difficult for her to walk a straight line.

Eleven years ago the right leg was, for a time, slightly numb, and for this she received electrical treatment and made a fair recovery.

Seven years ago she had a burning pain in the lower part of the back. Before the onset of this pain she could go about, but only to a limited extent, and she was then confined to her bed for four months. On getting up again she could not walk at all, except with assistance. During this period there was no pain in the legs.

Five years ago she had two congestive chills in no way affecting the condition of the legs.

Three years ago, under the scapula and in other portions of her back, she had a sensation as though a boil were present.

A year or so ago, slight sciatic pains were present at times, with a like pain posterior to the inner malleolus.

During the summer of 1888, she had an attack of severe shooting pains around the thigh and along the sciatics. She then had hyperæsthesia of the skin and had the leg protected by down pillows, so painful was every touch. This spell lasted one week. When attempting to walk, her feet seemed to stick to the floor. She could not walk at all in the dark, and she had a sensation as though she must watch every step; but this sensation has gone. Numbness is not a prominent symptom, only occurring after the leg has been hanging for a time. For the last year she has not been able to walk, and has now lost all power of leg motion when lying down, being then unable to stir any part of the lower limbs. A year ago she was better at times, but the improvement lasted only for short periods. The disease showed throughout a gradual increase.

Present condition: The hair is brown, the skin dark, and shows no signs of eruption. The legs are slightly œdematous. The teeth are good, with no changes except the suspicious blue line as above noticed. The tongue presents a light coat, though this is not always present. Appetite is good; digestion is fairly natural. The bowels are regular. Rectum not examined. Lungs normal. Pulse is regular, 64 per minute; not very full. Arterial tension not increased. Blood not examined. There are no evidences of disease in the abdominal organs.

The only clinical symptom present of gynecological importance is too frequent occurrence of menstruation—once in three weeks. The uterus is slightly enlarged, movable, and in good position. No trouble in either broad ligament, and the cervix is quite healthy, with the exception of some few granulations. The uterus is of lax fibre.

Nervous system: Her general intelligence is good. She sleeps well. Her strength is good above the waist. She has a lack of complete control of the bladder, and the urine will sometimes come away suddenly; occasionally there is some dribbling, and the tendency to sudden discharges applies to the rectum also. She has no vertigo, but her station is not good; she cannot stand alone. She cannot walk forward at all, nor can she move a muscle, from the hips down, in either leg. When standing she can move the thighs a little with the psoas muscles. She can walk backward a few steps with full assistance. Her legs are fat and apparently in good condition. The feet are cold now, but sometimes they are warmer. Occasionally tremors occur, which are coarse and rapid and confined to the legs. They first appeared in the right leg five years ago.

Reflexes: Sole +. Epigastric reflex is present.

Tendon- and muscle-jerk: A blow upon the patellar tendon, when the leg is in a semiflexed position, causes markedly increased jerk and so-called spinal epilepsy. Bending the ankle abruptly causes no paradoxical contraction. Bending of either big toe causes contraction of the ankle and of the quadriceps extensor femoris above. At the ankle there is clonus on the slightest flexion. Pricking of the skin of the leg causes immediate reflex motion. Clonus can be had at each knee, with the leg in extension, by pulling at the patella; but it cannot be had when the leg is bent, there being apparently too much tension of the muscles. When the leg rests across a support at the knee, it fails to drop at once, and, on attempting to bend it, is found to present perfectly the "lead-pipe condition;" and, after being held for a time in extension, it slowly falls. Having the knee slightly bent and making the slightest blow with the hammer on the patella, so that no response is obtained, a marked response is obtained by clutching the hands. Both right- and left-hand contractions give this reinforcement, and, likewise, contraction of the muscles of the face. Both Dr. Lewis and myself satisfied ourselves separately as to this point.

No reinforcement can be had by pain, or cold, or heat, applied to the legs or arms. The leg muscles react under the blow of a hammer excessively and very rapidly above and below the knee, and with no local humping. A blow on the gluteal muscles causes violent thigh clonus. Paralysis of the legs is complete. There is no pain present, but on making abrupt extensions pain is marked; and on thus extending the left leg, there is a sharp pain on the outer part of the right thigh.

Touch and localization seem perfect on each side, though the patient thinks that they are rather less perfect on the left side. The sense of pain is normal. There is some confusion in the feet as to temperatures; she distinguishes heat easily, but sometimes mistakes cold for heat. There are no subjective sensations, and no trophic alterations, save slight œdema. There are no hallucinations and no hysterical symptoms whatever. She has no headache. She thinks there is some soreness over the nerve trunks below the knee on deep pressure.

The examination of the eyes by Dr. de Schweinitz is as follows: Pupils act normally; external muscles normal, except some slight insufficiency of internal recti; fundus of each eye normal; only slight retinal haze around edges of the disk. Patient has no asthenopia.

The ears show no changes. The urine is acid and of high color, specific gravity 1031; no albumin; no sugar. Microscopic examination shows a few pus cells, vaginal epithelium, and large crystals of uric acid, which are not very abundant.

All the electrical reactions are normal, and electricity causes no spastic reactions, unless the current is most excessive.

The preceding attacks of pain, numbness, etc., might excite suspicion as to hysterical tendencies, but there were no further, and, indeed, no distinct evidences, and I have rarely seen anyone more free from the obvious personal peculiarities characteristic of hysteria. Her spinal system, however, seems to have been sensitive, and, at last, comes a complete history of lateral sclerosis, with involvement of the direct anterior columns to an extreme degree. We have entire paralysis from the groin downward; excessive spastic conditions; perfect sensation in all forms; no more bladder trouble than some spasticity may cause. The knee-jerk is, of course, in excess. If we excite it feebly, voluntary acts of either hand, or of the face, increase it; therefore, the channels by which reinforcements attain to the ganglia involved are open—not so freely as usual, but distinctly enough. The volitional force cannot reach these centres; the reinforcements can. If we admit "overflow," involuntary tracks are still open to this. Or, if we say with some that a voluntary act releases the concerned spinal ganglia from superior control, the tracks of such influential control must still be open. The problem does not gain in clearness, and I must admit escape of some one band of fibres from the ruin which seems to have fallen on the mass of anterior and lateral fibres.

Not less puzzling is it, in any theoretic point of view, that the sensory reinforcements fail where the motor remain. If we seek explanation of reinforcements in overflow, we must, of course, presume that sensory reinforcement-overflows are somewhere arrested on their way to the motor reflex spinal centres; or, if we insist on the inhibition view, the inhibitions due to sensory impressions must be cut off, so that it is fair to infer that they are nowhere above the level of the said ganglions switched on to motor tracks.

I pointed out in a lecture last spring that in a case of Professor Osler's, of broken back, there was no knee-jerk and no volitional control of the quadriceps, and yet that I could, at least, evolve slight knee-jerk during violent clenching of the hands, and coincident grimace. The will-channel was shut, the reinforcement-channel open.

It has always struck me as most strange that electric movement of muscles was non-reinforcible, and this seemed to me a proof that electrical influence is the most local of all stimulants to muscles. And of this there are other proofs, and none better than the fact that while in these spastic cases a pinch, a pin-prick, almost a mere

touch, arouses reflex action, considerable electric irritation may fail to do so.

My friend and colleague, Dr. Morris Lewis, has kindly furnished me with the following notes of a case under his care at the Children's Hospital. In this instance, a child, aged seven years, was completely paralyzed as to motion, and partly so as to sensation, but the knee-jerk was reinforced by a grimace or clenching the hands, and also by a pin-prick on the face or hands.

Rose C., aged seven years. Her father had syphilis, but there was no history of phthisis. Previous to her illness Rose had had whooping-cough, croup, measles, and chicken-pox. She seemed perfectly well until June, 1889, when a "hump" was noticed high up in her back. Last July she had a fall, which weakened her back for awhile, but she soon recovered, and played around with other children. On October 2d she had a second fall, which completely disabled her, and she was put to bed. Paralysis of the legs, bladder, and rectum came on immediately after the fall. A fortnight later a bad cough developed, which was worse at night; breathing was rapid and noisy. On October 30th she was admitted to the hospital. Her pulse was 140, and temperature 99°. She had had two convulsions two days previously.

Five days later her general condition was much improved. There was slight knee-jerk present in both legs reinforced by a grimace, clenching the hands, and by a pin-prick. No ankle-clonus. Area of acute sensation above a line drawn around the body about three inches above the umbilicus.

When seen November 3d, the child was breathing entirely with the diaphragm, the respiratory muscles appearing to be completely paralyzed. The lower portion of the chest-walls sank with each respiration, as did also the intercostal spaces.

Ten days after admission knee-jerk was obtained in the right leg after a few trials, though not in the first attempts, reinforced by sensory and voluntary motion. Ankle-clonus absent in both, though obtainable two days previously when the temperature was two degrees lower, viz., 98.4°. The lungs had then cleared, excepting for a few large râles. No dulness anywhere.

There were two decided prominences in the upper dorsal spine apparently belonging to the first and second dorsal vertebræ. Immediately below this prominence there was a lateral curve with convexity to the right. The skin over the prominence was intensely sensitive to heat, more so than the skin elsewhere.

The treatment adopted by Dr. Lewis was at first the use of carbonate of ammonium and digitalis, followed by cod-liver oil and syrup of iodide of iron. Extension in bed was employed; a three-pound weight was attached to a pulley at the foot of the bed, which was slightly elevated. Attempts at extension in the upright position failed, because of the distress to the patient. Now, however, six pounds twice a day for five minutes can be borne, and although sensation has improved immensely and she localizes well, there is no return of motion. Knee-jerk is obtainable with difficulty, and there is reinforcement, though feeble; it is best in left leg. But it is sufficient proof that, though the will-channel is shut, a reinforcement-channel is open, and a pathway of hope for an ultimate cure.

I wish to call your attention to the points of resemblance and of difference in these two cases. In both sensation in the affected limbs is good. In both the will-channel is closed. In the first, motor reinforcement is possible, while sensation failed. In the last case the way for sensory and motor reinforcements is open.

Despite the fact that it is impossible in these cases to say exactly through what tracks reinforcements pass to reach the concerned centres, I am glad to mention such facts as we do know, trusting that other physicians may be more fortunate in seeing cases which will enable them to ascertain with exactness the facts we now desire—that is, the true paths followed by motor and sensory reinforcements.

I have long sought for cases of crushed spine to see if, in absolute isolation of spinal centres, it be possible to obtain by heat or cold mechanically used below the injury any reinforcement of the knee- or ankle-jerk. The chances to see these cases usually fall only to general hospital surgeons, and of late no instance of this accident has been within my reach.

REFLEX NEUROSES.[1]

BY M. ALLEN STARR, M.D., PH.D.,
CLINICAL PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

THE active part of the nervous system is the gray matter. The white fibres merely carry impulses to and from it. This gray matter is collected into three quite distinct masses: (1) the spinal and medullary centres—*i. e.*, those from which the spinal and cranial nerves arise; (2) the basal ganglia; (3) the cortex. In the entire vertebrate species it is possible to assign to these distinct masses different functions: to the spinal and medullary centres reflex action, to the basal ganglia automatic action, to the cortex conscious and voluntary action. In dealing with reflex disturbance it would, therefore, at first appear that we were to be limited in our discussion to affections of the spinal cord and medullary centres. These must certainly be considered. Yet we are not thus limited. For each lower system is under constant control from the one above it; hence the spinal (reflex) activity being the lowest is dominated both by the basal (automatic) activity and by the cortical (voluntary) activity. Hence, disturbances of reflex action may be brought about by anything which either increases the normal inhibitory action of the higher centres or removes that action, as well as by disease of these reflex centres themselves. A prompt motor response to a sensory stimulus is the action which should normally take place when the reflex centres are called into play. Sneezing, winking, swallowing, coughing, the secretion of alkaline saliva in the mouth, and acid gastric juice in the

[1] Read at the New York Academy of Medicine, March 20, 1890.

stomach, when any foreign body is put into these cavities, the act of vomiting when that body is an active irritant, or of increased peristalsis of the intestines if the foreign substance reaches it; the flushing of the skin with blood when exposed to changes of temperature, the regular respiratory and cardiac movements, and the vascular tone: these as well as the so-called tendon and skin reflexes are examples of reflex activity. Without such reflex action the balance of supply and demand in the human economy would be impossible and life itself would cease. A power of quick and appropriate response to normal or abnormal irritation is a natural power of the lowest masses of gray matter. I cannot find any evidence from the study of disease that the exercise of this power is in any way detrimental. This power may be interfered with in several ways. Strychnine and its coefficient drugs will increase it. The result is manifest (1) by an unnaturally strong response to a weak irritation; (2) by an abnormally long and continued response to ordinary irritation. The spasms on slight touch and the opisthotonos with rigidity in a guinea-pig poisoned by strychnine are examples of both. In man tetanus furnishes a good illustration; but the extraordinary state of nervous irritation, the starting and jumping at little noises, the flushing on slightest irritation, the cramps produced by heat, the extreme uneasiness and hyperæsthesia present in spinal meningitis are equally good examples of increased reflex activity due to direct irritation. Reflex activity may be suspended by violent and sudden irritation. Injuries to the abdomen or head may arrest all reflex activity and cause death in man as well as in a frog, as described by Goltz. It may be impaired by an excess of moderate irritations coming simultaneously. Just as the conscious attention cannot be given at one time to several subjects and elicit simultaneously appropriate responses to all, so reflex centres may be embarrassed by numerous simultaneous stimuli and fail to react to any one in proper degree. The condition subsequent to severe traumatic concussion is an illustration.

When we seek for illustrations of either increased or decreased reflex excitability from spinal disease it is evident that we must allude to very serious diseases. The reflex mechanism is too important and too stabile to be affected by little irritants, or by slight causes. If it were not, the numerous, inevitable stimuli consequent upon an active life would constantly put that life in danger. How few of the severe accidents which constantly occur really affect in any marked degree the reflex nervous system? How many serious irritations, traumatic, painful, distressing, fail to cause a single spinal nervous symptom? The surgical wards of a hospital offer little field for the observation of reflex nervous disturbance—happily for the inmates. In the lower animals such affections rarely exist.

Turning now to the other cause of disturbance of reflex function, defective control by higher centres, we at once enter upon a broader field. Arrest of reflex activity is rare and needs little consideration. It may be produced voluntarily, as one may prevent the knee-jerk by intention, or inhibit the act of swallowing, as in hysterical dysphagia. It may be produced involuntarily, as when cerebral hæmorrhage inhibits respiratory or cardiac action; or extreme fright causes death in the same way. Increase of reflex activity from central causes is common. The act of control must be constantly exerted in order to preserve the balance of power and the proper harmony of action in the nervous system. Whether we start from a consideration of moral conduct or of the plantar reflex we reach the same conclusion. And in central control a slight defect produces widespread and serious results. A man who has once abused a confidence will not be implicitly trusted, though he lives for a hundred years. A small clot in the brain will set all the motor, vasomotor, and sympathetic centres in such a state of instability as to impair all confidence in their action. A hemiplegic who has apparently recovered still has the increased knee-jerk. This may not in any way impede the action of the reflex centres. That is carried on exactly, accurately, satisfactorily, and its action does no harm. The emptying of the bladder as soon as it is full is a perfectly normal, satisfactory act on the part of the lumbar spinal cord, and active incontinence of urine is not a symptom that it is diseased. It is a symptom that impulses calculated to restrain the act till an appropriate time and place offers are prevented from reaching that normal reflex centre. There must be a proper harmony and succession of reflex acts with some definite order for the nervous system to fulfil its whole duty. And any defect in that order may cause effects which in other conditions would not be defects.

If these patent facts of physiology be accepted, I think we must conclude that in those diseases known as reflex neuroses, in which there is no real defect in reflex action, but only an undue or inharmonious reflex activity, the actual origin of the disease must be either in an excess of activity in the lower centres or a defect of control in the higher centres. As we have seen, an excess of activity is commonly called forth only by very severe causes; while a defective control may come from slight ones. Phenomena comparable to tetanus or strychnine poisoning are rarely, if ever, seen in reflex neuroses. In the various reflex neuroses in which peripheral irritation is the supposed cause of disease, it is my opinion that when peripheral irritation is the actual cause, nature indicates it by attracting attention to the seat of irrita-

tion by discomfort or by pain.[1] And when, as in very many cases, the source of the irritation is by no means evident, is only found, or supposedly found, by extraordinary effort, the probability is largely in favor of the assumption that the reflex neurosis is not produced by any direct peripheral irritation, but is the manifestation of a slight or serious defect of control by higher centres due to their impaired nutrition and consequent impaired activity.

Theories are attractive, but misleading. Experience is a better guide. In my own experience I am sure that a very large majority of the patients who present symptoms of reflex neuroses have been exposed to influences which undermine the strength and nutrition of the *entire* nervous system, have serious symptoms, not only of a so-called reflex character, but of defective central control; are to be regarded as suffering from functional or organic disease of the highest, most complex, most highly developed portion of the nervous system; and are not merely the victims of irritation in some peripheral organ.

We know that long since the notion of a reflex paralysis—such, for example, as a general paraplegia from a slight wound of the hand—has been abandoned, and these cases are to-day explained more satisfactorily upon the theory of mental shock rather than spinal irritation.[2] That they are rare, must be conceded Two surgeons of this city, of the largest experience, have told me that they have never seen a case. We are coming rapidly to the notion that the symptoms in the so-called condition of spinal concussion are really due to the same state of mental shock. The highest, most delicate, most easily affected centres of the nervous system, those which are the last to arise in the process of evolution are, as Hughlings-Jackson has pointed out, the first to fail in dissolution, are the easiest affected by sudden and unexpected mental irritation. How else can we explain the fact that, in a railway accident, passengers who are asleep rarely suffer from after-effects? Passengers who are awake suffer the immediate alarm and the subsequent symptoms.

The phenomena of hypnotic suggestion have proved conclusively that many so-called spinal neuroses are really due to defective cerebral control. It is not necessary to call such defect hysteria. Mental shock and mental worry may produce such an unstable state of the highest centres that their inhibitory action is removed, allowing lower centres to manifest unusual activity. In such cases, then, the actual manifestation may perhaps be in a lower centre, but the actual seat of disease is not necessarily there. It is in the higher centre, which controls the lower.

Let us take, for example, a case of so-called uterine reflex neurosis. The irritation from the organ reaches the lower spinal cord. If its centres are really excited to activity, we should expect such symptoms as occur in a spinal meningitis, viz.: hyperæsthesia of the legs and cramps and spasms of the calves, vesical and rectal tenesmus, and active incontinence of urine. But these are not the symptoms found. You do find pain and a dragging sensation in the back. This does not cause any manifestation of true spinal reflex activity. There is no evidence of such activity. It does produce a wearing discomfort, appreciated consciously; received, then, in the highest cerebral centres; exhausting them, and impairing their control over the lower, especially the vaso-motor, centres. Hence the headaches, general nervousness, flushings, feelings of heat, etc., symptoms of general instability of the lower centres, *not* of the lumbar cord centres themselves in particular.[1] It is a mistake to call this a reflex neurosis. It is a general nervous exhaustion, due to a peripheral pain. The actual spinal reflex centres have no part at all, or very little part, if any, in the complex of symptoms.

I think the same is true—*mutatis mutandis*—of eye-strain. Let an eye be actually strained by defective vision, defective accommodation, or muscular asthenopia, and the result is increased winking, watering of the eye, feeling of inability to use it, pain, heavy eyelids, possibly conjunctival hyperæmia; and in an animal under strychnine, nystagmus, or twitching of the ocular muscles—a phenomenon rarely seen in man—never seen, in my experience from the so-called strain of the ocular muscles. Every other muscle in the body, if much over-strained, will become irritable; the knee-jerk can be increased by exercise; the biceps twitches spontaneously after a weight is raised. Who has not felt the tremor of an over-strained set of muscles? Why is it that, in eye-strain of the external ocular muscles, nystagmus is never seen? A serious strain of the intra-ocular tension—such as occurs in astigmatism and hypermetropia—gives rise to discomfort, to voluntary effort to strain the eyes in using, to effects, in other words, upon *not* the centres governing ocular motion, but upon the conscious voluntary centres of the cortex, upon the centres of highest evolution, most delicate, most susceptible to slight effects. The result is cortical exhaustion, similar exactly to that produced by uterine or ovarian pain, or by pain anywhere, or by mental shock or mental worry.

Take, lastly, the so-called reflex convulsions from genital irritation in boys—due to phimosis, or concretions behind the prepuce, or to masturbation.

[1] See Medical Record, January 1, 1890.

[1] Goodell: The Abuse of Uterine Treatment. THE MEDICAL NEWS, December 7, 1889.

Such convulsions occur only in neurotic children. They are always preceded by mental irritability, they never occur without some evidence of cerebral irritation. It is rarely that any such evidence of spinal irritation, as frequent micturition, or cramps in the calves of the legs, attends them. The irritation, then, is acting upon the entire nervous system. The weakest part yields first. That part is the part which controls the other parts. The child is not suffering from reflex irritation. Irritation at the periphery is the cause only in part; a weak nervous system is the potent predisposing cause. And, unless this be strengthened at the same time that the peripheral irritation is removed, there will be a recurrence of the symptoms from some other apparently trivial cause, and he who treats these will never cure the patient. The same thing is true of genital irritation in adults. Spermatorrhœa, seminal emissions, atrophy of the testicles, exist unnoticed in many persons until attention is called to them, the mind dwells on them, the higher conscious emotional nervous system is irritated by worry, and then the symptoms of so-called sexual or spinal neurasthenia develop. The trouble is *not* spinal, is *not* reflex, it is cortical. Thus physiological investigation and careful clinical study combine to prove that while peripheral irritation may produce nervous symptoms, it is not directly through the lower centres, it is not by exciting reflex action. It is rather by producing exhaustion of the highest conscious centres which control the entire nervous mechanism. The largest engine is governed by a very small steam crank. A little motion of that will produce very great motion elsewhere. If the engine is whirling itself to destruction, do not attempt to stop the flywheel, do not catch hold of the binding straps, but turn off the steam by the little crank.

In any case of so-called reflex neurosis do not be satisfied by merely removing supposed peripheral irritation, but increase the nutrition of the entire system, give it food and drink, strengthen it by every possible means, baths, exercise, rest; regular, not hurried work in many directions, not in one only; and by tonics, to enable it to exert all its powers of control, and the peripheral effects will disappear of their own accord.

In the presence of a case of neurasthenia with peripheral symptoms, of chorea, or epilepsy, or hysteria, with sources of peripheral irritation present, go back of the apparently important symptoms to those of real causal moment, and the therapeutic results will be more satisfactory and more enduring.

ELECTRICITY IN CHRONIC PELVIC INFLAMMATORY DISEASES.[1]

BY J. M. BALDY, M.D.,
OF PHILADELPHIA.

IT is now some years since Apostoli began to treat inflammatory diseases of the pelvis with electricity. At first under the influence of the older pathology, or, more correctly, lack of pathology, he called these troubles *phlegmon*, *peri-metritis*, *para-metritis*, *cellulitis*, and by other familiar misnomers.

To-day he recognizes these same diseases under more correct names, and says he shall speak no more of peri-metritis, but of salpingo-ovaritis, whether complicating a pelvic peritonitis or not. In order that we may be sure that we are not discussing one condition of pelvic disease and Apostoli another, it may be well in the beginning to make ourselves perfectly clear on this subject. In the *Journal of the American Medical Association*, July 27, 1889, Apostoli says:

"Every salpingo-ovaritis will generally be suitable for the appropriate electrical treatment, and this should be the conservative method of choice; it is sovereign in catarrhal salpingitis, only calmative in tubercular salpingo-ovaritis, and in certain pus tubes may be of great service."

The only variety of salpingo-ovaritis I here wish to discuss is that which I presume he intends his catarrhal salpingitis to represent, for the reason that a pus tube, with the pus drained away, practically resolves itself into an advanced stage of this variety, and, therefore, need not be separately considered. A typical picture of the pathological condition (brought about in several ways) which I have in mind, is as follows: The Fallopian tube thickened and enlarged to two, three, or four times its natural size by inflammatory changes, the tubes cheesy or not as circumstances determine; the fimbriated end destroyed, all traces of the fimbria having disappeared, and a rounded smooth surface presenting in their place, most often with the ovary adherent to it; the ovary and tube displaced to a greater or less degree, generally and firmly adherent; as a rule, the tube is empty. With this condition the patient will present a history of sterility, pain, and general ill-health. A local examination will show, often only to an experienced finger, an enlarged tube going off from one or both sides of the uterine cornua. Sometimes the disease is easily made out by vaginal examination, at other times it is extremely difficult to detect, this difference depending on the amount of disease, the high or low attachment of the appendages, the amount of relaxation of the abdominal and pelvic tissues, and the amount of pain, actual or hysterical, experienced by the

[1] Read before the College of Physicians of Philadelphia, March 5, 1890.

patient. That this is one of the conditions treated by Apostoli is evident from his own words:

"It (the electrical treatment) should be continued until the patient pronounces herself cured of her symptoms, and until an examination has satisfied us that the anatomical change is considerable."

He distinctly excludes pyosalpinx and hydrosalpinx in this connection, and dictates that "surgical interference should never be resorted to until after all electrical resources have been exhausted." This is an additional proof that we are considering the same conditions, as no true surgeon attempts, excepting under rare circumstances, to interfere surgically unless the tube is destroyed. So we may consider that Apostoli has in mind just such cases as I have described, when he claims to relieve salpingo-ovaritis. In no part of the numerous contributions of Apostoli can I find that he distinctly claims to remove the organic lesions of a chronic salpingitis, and if any inference may be drawn from expressions bearing indirectly on this point, they are, that he does not pretend to accomplish this much. For instance, in the paper already quoted he cites "two typical cases." The first was under constant treatment for one year or more, the second for over five months. The history and examination of both cases showed that the patients were suffering from pelvic peritonitis, and that behind the peritonitis there existed diseased appendages, such as we are considering. Although he claims these cases as cures, at the end of the treatment in the first case:

"A deep exploration caused rather acute pain in Douglas's pouch. . . . The uterus was found to be slightly adherent to the sacrum. With a deep touch the right ovary could be felt, also the right Fallopian tube."

In the second case:

"On pressure, a slight ovarian pain in the left iliac region was observed; the uterus was normal, very movable laterally, but it could not be lifted without difficulty, on account of the posterior adhesive bands; some prolapse of the annexes, more pronounced on the left, with one tube in the recto-vaginal wall; no signs of salpingo-ovaritis."

From this comment, "no signs of salpingo-ovaritis," it will be clearly seen that Apostoli meant that he had cured the symptoms; that he did not remove the disease will be perfectly evident to any practical surgeon from the description of the local condition at the time of the patient's discharge, presumably cured.

The disciples of Apostoli are not satisfied to accept this ground as the limit of the possibilities of the electrical treatment of these inflammatory diseases, but out-Herod Herod, and make claims which they have utterly failed to substantiate.

Goelet, in a lecture on electricity in gynecology, delivered before the class of the New York Polyclinic (The Medical News, June 22, 1889), says:

"That in the treatment of these conditions he finds that *exudations and adhesions melt away like ice under the rays of the sun.*"

Massey, in his book on *Electricity in Diseases of Women*, p. 160, says:

"Whenever chronic enlargement exists, a shrinkage to the normal size is an invariable record, and adhesions as well as exudations are generally noted as disappearing."

Lapthorn Smith (*American Journal of Obstetrics*, August, 1889, p. 805) says:

"Those who operate for this condition tell us that they frequently find the ovaries and tubes compressed and bound down by a retracting plastic effusion; but, owing to the stimulation of absorption, these exudations are removed and the ovary is left free."

Many other electricians write in much the same strain. Now it is just this difference between Apostoli and his disciples to which I desire to call attention. Apostoli is by all odds nearest the truth, but even he has gone a little too far, and will undoubtedly in time modify some of his statements. My own position on this subject is quite clear, and is based on a large clinical experience, a by no means small surgical experience, and by a most careful observation for two years or more of the electrician's work in these diseases. By this I mean that I have daily, during that time, stood by the side of experienced electricians, examined the cases when they first came for treatment, examined the patients during its continuance and to the end, and have seen many of them at varying times after they had been pronounced cured or had ceased to come for treatment. In all this time I have failed to observe a single cure of the disease. By this I do not wish to be understood as saying that I have not seen patients relieved of their symptoms and sufferings, for such a statement would not be true. I have observed a number of cases after a protracted course of treatment, during which some of them were at times much worse, become so much better as to express themselves as satisfied with the results; and yet they almost invariably returned with a relapse, or I would accidentally stumble across them in some other clinic seeking if they might not obtain the cure they had failed to obtain from electricity. Again, I have seen patients made worse during and by the treatment, and have on several occasions become cognizant of some of them who have been confined to bed for a week or more with an attack of peritonitis. I have in mind one recent case, who, after three months' treatment, and during the continuance of the treatment, became so afflicted. She came from her bed to me for relief, and refused to go back to electricity. She will be operated on

shortly. I could add a dozen or more cases who have absolutely refused to try the remedy a second time.

I will not burden my paper with a detailed account of a number of cases, but will satisfy myself with the full account of one case. I think I shall be able with it to bring out all the essential points and prove by it as much as could be done by many such. I have selected this case from a large number of similar failures which have come under my observation :

1. Because it so well represents the class of cases under discussion.

2. Because the treatment extended over so great a length of time (sixteen and one-half months), and the operation was not made until the electricians admitted they could not cure her.

3. Because she was treated by Dr. Massey himself, a gentleman who is quoted as an expert in this method of treatment, and therefore the failure cannot be attributed to a faulty application.

4. Because we can so accurately study the different steps of the disease and treatment during its course, and have been enabled to verify all our conclusions, and demonstrate the results with the specimens in our hands.

The case stands as an excellent type of all its kind, and the results of treatment of the kind will always be the same. The cases quoted from Apostoli's paper will be found to result in the same manner if they are followed up.

In Dr. Massey's book on *Electricity in the Diseases of Women* (Case XVI., pp. 161, 162) the case to which I would direct your attention is reported, and in order that I may not be tempted to exaggerate the patient's symptoms, I will quote the report verbatim :

"E. C., aged twenty-six years, married, a native of Poland, was referred by Dr. Bradford, Sept. 27, 1888. She had had three children and one miscarriage, the last pregnancy four years ago, since which time she had been in continuous pain, and had grown progressively worse. For the last four weeks she had been particularly bad, a sanguineous discharge having been constant. There is absolute dyspareunia, and any jar causes intense pain. Menstruation has been regular, normal in amount, attended with severe exacerbations of pain, followed by scanty yellow leucorrhœa. Examination shows uterus enlarged, somewhat anteflexed, and with fundus displaced to the right. Sound enters three inches with difficulty, producing excruciating pain. To the left of the fundus a mass is made out, consisting, apparently, of the ovary bound down by adhesions. The patient's physiognomy indicated intense suffering at every step."

From September 27th until November 13th, a period of about a month and a half, this patient was treated with electricity. Her condition at the end of that time is noted in the above quoted book (p. 163) as follows :

"Uterus measures two and a half inches, with fundus somewhat to right. The mass to the left is scarcely discernible, and the ovary can be detected higher up. Still under treatment."

In a letter written by Dr. Massey, in answer to a criticism on his book, in the *Annals of Gynecology*, August, 1889 (p. 528), he again referred to this case, and I here reproduce what he said at that time (eight months after the first report of the case) ; the case having in the meantime been under pretty constant treatment :

"The critic's oracular statement, 'that any attempt to melt away pelvic adhesions and indurations, other than simple congestion,' by electricity 'is futile and harmful,' is somewhat wide of the mark. No one attempts to melt these adhesions by the direct polar action of the current as they evidently suppose. The methods adopted include the morbid products within the interpolar zone of a galvanic current, and by cataphoric action promote their absorption. This treatment is necessarily tedious in many cases, but, if faithfully pursued, will lead often to most brilliant results. The ultimate result in Case XVI., in which there was a prolapsed ovary surrounded by exquisitely sensitive adhesions and indurations of four years' duration, is an excellent illustration of this fact, but was not related in the work, as the patient was still under treatment at the date of going to press. This patient had declined operation at the hands of one of the critics, and during the electrical treatment at the Pennsylvania Hospital was repeatedly examined by competent surgeons, who predicted failure. She has now been in the enjoyment of perfect health for some months, discharging fully all duties to her husband and children, even to doing the family washing. This case deserves particular mention, as it was the subject of sceptical criticisms at one of the medical societies while the treatment was in progress."

Within a few weeks after the above report the patient was back with a return of all her old troubles. After some weeks' treatment she was again discharged as cured, only to return in a short time as bad as ever. In the next few months she had periodical relapses, of which she was relieved at times by electricity, at other times by the ordinary gynecological resources. At the last relapse, Dr. Massey said, that if he did not cure her permanently this time, he would consent to an abdominal section being made. After weeks of electrical treatment—and during its progress she voluntarily came to me stating that she was getting no better, that she could bear her sufferings no longer, and that she would submit to the operation if I would perform it. On Friday, January 17, 1890, with the assistance of Dr. Bradford, and in the presence of half a dozen other gentlemen, I made an abdominal section and removed both tubes and ovaries. The omentum was adherent over the pelvic inlet, and required considerable manipulation to free it. Everything below it was adherent. One tube and ovary were curled up into a mass, and adherent on top of the fundus uteri. On one side there was a subperitoneal cyst containing a few drachms of serum, which was

ruptured during the manipulation. On the other side the ovary was distended with about half an ounce of bloody fluid. Both tubes were two or three times their natural size, very hard, and indurated. There was no trace of the fimbriated ends in either tube, the fimbria and ovaries being blended into one. The patient made an uninterrupted recovery and went home at the end of two weeks. To-day, over six weeks after the operation, she is without a sign of her old pains. What will be the subsequent benefit to the patient can, of course, be only conjectured, although I have every reason to expect, from past experience and present indications, a permanent cure. However, this is not at all material to the present discussion, my object being to show that *electricity will not cure chronic adhesions and organic disease of the uterine appendages*, rather than to prove that surgery will.

Four years before this patient applied for treatment, she had an attack of post-puerperal trouble, which resulted in an occlusion and destruction of both tubes, a general adhesion of all the contiguous pelvic serous surfaces, and was possibly the starting-point of the ovarian cystic disease. Whether there was pus in the tubes originally, I know not; there was none when she first came for treatment, and none at the time of the operation. With the exception of the pus, the tubes look in all respects like pus-tubes, and are in just such a condition as pus-tubes after the pus has been evacuated. The post-puerperal trouble finally subsided, leaving the appendages destroyed and adherent. After a lapse of time, owing to some indiscretion or exposure, an attack of pelvic peritonitis was set up as a complication. These attacks were repeated and became worse, and during one of them she made us her first visit. This was in September, 1888. After about five or six months' treatment, during which she was distinctly worse at times, she obtained relief, and was discharged cured, and was so reported by Dr. Massey in his letter to the *Annals of Gynecology*, August, 1889. She remained well for a number of months, and then, owing to another indiscretion or exposure, was attacked by another pelvic peritonitis. She remained well for only a few weeks this time, and then had repeated attacks at short intervals, until, finally, after sixteen and a half months, she was so worn out that she asked for an operation, which she had at first refused. During all this time her original disease (chronic adherent salpingitis) remained, and was in no wise affected by the treatment, unless it was made worse. I say made worse, because her old family physician, Dr. Raynor, examined her a week before the operation, and states that the disease was markedly worse than when he last saw her, one year and a half previously, since when she had been almost continually under electrical treatment.

What did the operation show? A condition of disease and adhesions which demonstrated most positively and conclusively that "the methods adopted" for her relief did not "include the morbid products within the interpolar zone of a galvanic current, and by cataphoric action promote their absorption," as was claimed. It proves beyond dispute, that not an adhesion was disturbed, and that the tubes themselves had not even begun to show any alteration for the better. There was the disease, and there it stayed. If the local disease was as bad as ever, what, then, happened to give her that interval of several months of apparent cure? As I said before, she had had repeated attacks of acute pelvic peritonitis complicating the chronic organic disease. It was the acute peritonitis which was relieved, but which just as surely came back on the slightest provocation. Now, this is just the point which I wish to emphasize. Electricity, properly and carefully applied, will in time relieve the pain of the pelvic peritonitis, but under no circumstances can it influence for the better the resultant chronic adherent salpingitis of the original attack. The first attack destroys the tubes, and every subsequent attack makes the chronic disease worse. If one is satisfied simply to relieve his patient of the inflammatory attacks as they occur, and to have them keep on returning with repeated sufferings, he can turn to the electrical treatment. He will, however, find this a particularly slow method, and will discover that often he can relieve his patient more quickly by hot water irrigations, glycerin tampons, and the free use of purgatives, combined with other well-known gynecological and general methods. If, on the other hand, he wishes to cure his patient permanently, he must remove the chronic disease which is the cause of the acute or subacute attacks; in other words, he must remove the uterine appendages. There is absolutely nothing short of this, in a certain number of cases, which will accomplish the desired end, and I am sorry to have to confess that this fails only too often.

Many women go for years after the disease has originated before the repeated attacks of peritonitis begin. During this interim the disease seems to remain latent, and does not give unbearable suffering. During this period a moderate amount of ordinary personal hygienic care will keep the woman in comparatively good health, and she may never reach the period of repeated attacks of peritonitis. But, if they once begin, the woman, especially the working-woman, knows few weeks of comfort. As a rule, the danger to life is not great, but the constant suffering is extremely wearing, and the patients do not need much urging to undergo an operation in

order to obtain relief. At any rate, electricity is absolutely powerless to cure them. The burden of the proof remains with the electricians. If they would convince those of us who have no faith in their methods, they must select their cases carefully, have them examined repeatedly by recognized and competent diagnosticians, and then, when they are through with their treatment, satisfy us that they are actually cured, and not simply relieved. It will not do that they should take a case in one of the periods of pain, relieve her of that pain, and pronounce her cured, even if she has no relapse for some months, or even a year or more. I have observed many of these women who have had their disease for four, five, or more years, and during that time had only two or three attacks of peritonitis. They had been under no kind of treatment whatever, and, therefore, their immunity cannot be attributed to treatment. If, however, this immunity should occur after being relieved by electricity, it would be, and is, claimed as a cure. As a matter of fact, all the cases reported cured by this method have gone on record within a few months after the completion of treatment.

I do not mean to say that all cases of chronic adherent salpingitis should undergo an abdominal section, because I am becoming more and more convinced that entirely too many operations are made for this disease. If a woman is in good circumstances, and can have ordinary hygienic and dietetic care combined with slight medication from time to time, she can, in the majority of cases, live a comfortable life. It is of the minority I speak, when I say that abdominal section is the only cure.

There is one other point on which I would touch. The electricians triumphantly state that when they begin their treatment there is great pain and suffering, large masses can be felt in the pelvis, and that as the symptoms subside under treatment these masses also fade and disappear. Such was the state of affairs in the cases quoted from Apostoli, and also in the case I have reported above. Now what is the explanation of this? With every attack of acute pelvic peritonitis there are large quantities of plastic exudates thrown out, and a vaginal examination gives the impression to the finger of hard, board-like lumps. So often have I mistaken these temporary exudates, which almost always disappear with the subsidence of the inflammation, for large chronically diseased tubes and ovaries, that I now never give a definite and decided opinion until I have had an opportunity to treat the case, and am able to see what is temporary and what permanent trouble. Until this is accomplished, it often takes a very well-trained finger to decide how much actual chronic disease exists. Here is a point of failure with the electricians. They get rid of the acute exudates, relieve the pain, and pronounce the patient cured, only to have them come back, or go elsewhere for treatment. The vast majority of these men are not trained in gynecological examinations, and have never done an abdominal section. I feel most strongly that no man is or will ever become a reliable diagnostician in these diseases until he has had his fingers on the disease both from below through the vagina and from above through the abdominal wall. It is well nigh impossible to gain an accurate knowledge of the condition of affairs in a pelvis ravaged by a septic or specific inflammation without having had one's fingers in a few such pelves and without having attempted to tear out the diseased parts.

What place, then, do I give electricity in the treatment of this class of diseases? Simply that of a therapeutic agent, which will mitigate, but which will never cure. I class it with glycerin, tampons, hot water injections, purgatives, etc., and I consider it the least valuable of them. The relief I have observed from electricity has been exactly what I have obtained from these other remedies, with this difference, that electricity is somewhat slower in its action. However, I must admit that I have seen electricity relieve where I had failed with other remedies, and *vice versa*.

Electricity, I would hold, if I had determined on mere palliation, as a last remedy, for the following reasons:

1. The treatment must be a local one, and must be given by the physician himself.

2. The apparatus is too expensive for any but a specialist to possess.

3. The patient must submit to a prolonged vaginal manipulation several times a week, sometimes for months.

4. It is necessary to remove a great part of the woman's clothing in order to administer the treatment properly and thoroughly.

The absolute failure to cure the disease, which I have shown in the above case, I could easily demonstrate in many others.

328 South Seventeenth Street.

TUBERCULAR ULCERATION OF THE INTESTINES.

Report of a Case of Osteitis of the Hip, Dying of General Tuberculosis. No Intestinal Symptoms during Life. Autopsy.[1]

By V. P. GIBNEY, A.M., M.D.,
SURGEON-IN-CHIEF TO THE HOSPITAL FOR RUPTURED AND CRIPPLED, NEW YORK; PROFESSOR OF ORTHOPÆDIC SURGERY, NEW YORK POLYCLINIC.

The following autopsy was made on a boy who had been an inmate of the Hospital for Ruptured and Crippled for about eight or nine months. He

[1] Presented at the meeting of the State Medical Society in Albany, February, 1890.

was admitted for the relief of deformity, resulting from old disease of the hip, tubercular in character. He came from a Western State and was in very fair condition at the time of his admission. It was my intention to do Gant's operation, but on examining more closely I found two or three open sinuses around the upper portion of the thigh, and I determined to postpone the operation, hoping that these sinuses would close. A splint was applied, which protected the joint, and he was soon going about apparently with less deformity. The sinuses continued to discharge, however, and in the latter part of the year 1889 he began to fail, and developed pulmonary tuberculosis. Full notes of his condition and symptoms were kept, and neither the trained nurse nor the house surgeon remembered that there was any diarrhœa or dysentery during his entire stay in the hospital. The examination was made by Dr. Holt, on the 25th of December, fourteen hours after death, and is as follows:

Body much emaciated. Head not examined. Lungs, no adhesions; no fluid in the pleural cavity. Both lungs closely studded with recent miliary tubercles; about one-third of the left upper lobe consolidated. On section, this area shows some cheesy nodules the size of a pin, and two or three minute cavities containing pus. The posterior portion of the upper lobe of the right lung shows a similarly consolidated area of smaller extent, giving a singular appearance upon section, but not quite so far advanced. There are smaller and larger areas of pneumonic consolidation throughout both lungs.

Bronchial glands are enlarged to about one-half inch in diameter; one or two are slightly cheesy; one partly calcareous; none broken down.

Heart: No tubercles on the pericardium; walls and valves normal; recent dark post-mortem clot filling both auricles and ventricles.

Liver slightly fatty; has a mottled appearance; no waxy change shown by iodine test; a few miliary tubercles on the surface.

Spleen slightly enlarged; not very consistent; tubercles upon the surface.

Kidneys normal. Stomach normal; capacity thirty-two ounces.

Small intestine: From above downward large transverse ulcers are present at intervals of two or three feet, the average size being one-half inch wide by one and one-half inches long, oval in shape, some nearly encircling the intestine, deeply excavated, and involving the muscular coats. Edges thickened and reddened, showing an active ulcerative process. Upon the peritoneal surface there is puckering, showing cicatrization; in one or two ulcers this is marked enough to produce a considerable diminution of the lumen of the intestine. In many places miliary tubercles are seen upon the peritoneal surface; no perforations. The largest ulcers are just above the ileocæcal valve; these are one and one-half inches wide and two and one-half inches long, and one surrounds the margin of the valve. There is considerable localized inflammation of the peritoneum covering the intestine in this region, and it is studded with miliary tubercles, the ulcers in almost every case beginning within Peyer's patches. The solitary follicles throughout the small intestine are enlarged to about the size of a pin's head. In the upper part of the small intestine the mucous membrane generally is healthy. In the lower two or three feet there are evidences of quite an intense enteritis, congestion, swelling, and œdema.

Large intestine: Two or three tubercular nodules, reddened, elevated, and broken down, but no ulcers; mucous membrane normal.

Mesenteric glands about one-half inch in diameter; a few are cheesy, and one entirely calcareous.

The diseased hip: Thigh is adducted; trochanter raised; two or three open sinuses on the inner aspect of the upper third of the thigh. The upper six inches of femur with a portion of the pelvis, including the acetabulum, removed. A specimen was then sawn open through the great trochanter and neck and shaft of the bone. The head of the femur was completely disintegrated and absorbed. About one-half of the neck of the femur remains, and thus forms a sort of articulation with what is left of the acetabulum. There is a pathological dislocation; small areas of broken-down osseous tissue are present at the upper and lower borders of the neck of the femur, but the general outline of the hip-joint is almost entirely obliterated. The capsular ligament seems to be intact. The shaft of the bone is healthy; no osteomyelitis. Bacilli very abundant in specimens taken from hip.

CLINICAL MEMORANDA.

MEDICAL.

A Case of Morphine-habit without Injurious Effects.— Divers writers, both lay and professional, have depicted with sufficient eloquence the horrors of the morphine-habit. It has been declared to derange nearly every function of the body; to cause paralysis of the will; to make the truthful mendacious, and much more which is familiar to every student of the subject. These statements have, for the most part, been accepted as the whole truth of the matter, and their universal applicability has not been seriously questioned. Nevertheless, Dr. B. W. Richardson, in the *Asclepiad*, has recently given the details of a case in which a man, sixty years of age, appeared after ten years' use of the drug to have derived therefrom considerable benefit. An equilibrium seemed to be established by the morphine which had hitherto been lacking, and the result was better general health and greater capacity for intellectual work.

A case even more remarkable has been under my observation for the past eight years. Every possible opportunity has been afforded me to study this case in all its bearings, and to verify every statement. The history is as follows: Mrs. X., widow, aged sixty, has been using morphine for seventeen years. She began its use at the age of forty-three, on account of insomnia, and has gradually increased the dose up to seven grains per day; but during the past year the dose has remained stationary. Notwithstanding her age, her complexion is fresh, her step firm, her carriage erect, her appetite good, and the functions of stomach and bowels perfectly normal. She enjoys seven or eight hours of dreamless and refreshing sleep every night.

Although possessed of considerable property, she is from choice constantly engaged in active labor, and, indeed, accomplishes an almost incredible amount of work without feeling exhausted; in fact, her general health is better now than ever before. Careful observation, aided by a long personal acquaintance, has failed to show any sign of that moral degeneration so strenuously insisted upon by authors. She is especially devoted to charitable work, and is very zealous in religious matters. Her affection for her children and grandchildren is intense, and sacrifices are freely made on their account. In her demeanor she is calm and dignified, and presents no sign of irritability or other mental deterioration. As in the case recorded by Dr. Richardson, she is perfectly satisfied with her present condition, and feels no necessity for reformation.

O. H. Merrill, M.D.

Corrinna, Maine.

SURGICAL.

A Case of Subcoracoid Dislocation of the Right Humerus, and Compound Comminuted Fracture of the Forearm.—The following somewhat unique injury happened when I was on duty as Hospital Steward U. S. A., at Fort Barrancas, Florida. It is of interest, I think, considering the youth of the patient, and the good recovery that took place without any untoward symptom, and it shows very clearly the good results that occur from the simplest treatment for such a grave injury.

On the afternoon of Sunday, the 15th of September, 1889, G. J., a child six years of age, white, was brought to me at the Post Hospital by its mother. I was informed that the child jumped on the car which was used to haul supplies, etc., between the wharf and the post. The mother started to run the car down the track, but the child, becoming frightened, jumped off whilst the car was in motion. In jumping, his foot caught in a loose nail on the floor of the car, and he fell headlong on the track. He partly rolled over on his side, thus saving his head and chest, but one wheel went over his right arm. He was at once picked up and brought to the hospital.

I saw him about twenty minutes after the accident. There were no perceptible signs of shock. Placing him in a chair, and cutting away his shirt, the following injuries were observed: The right arm was hanging by the side, the elbow away from the body, while the inclination of the patient's body was toward the injured limb. Standing behind him with my two hands laid flat on each shoulder, with the forefingers on the acromion, and pressing the other three fingers firmly in under the process, it was at once apparent that the head of the humerus was not in place, the hollow under the acromion being clearly marked. Further examination showed that the head of the bone was lying under the coracoid process upon the anterior part of the neck of the scapula. In short, it was a well-marked case of subcoracoid dislocation of the humerus. There was a punctured wound about the size of a ten-cent piece, over the brachialis anticus, with slight hæmorrhage, and a compound comminuted fracture of the right forearm. Crepitus could readily be obtained. Careful examination of the head, neck, and chest gave negative results.

There being no medical officer at the post, and knowing that the first and principal indication was to replace the bone in its normal situation as speedily as possible, I proceeded to do so. No anæsthetic was given, as I considered that I was not justified in taking that responsibility without skilled medical attendance. I had four ways in which to reduce the dislocation: First, by the heel in the axilla; second, by the knee; third, by drawing the arm upward; and, fourth, by manipulation; and, after some thought, I choose the fourth method, my reason being that no violence whatever should be used, and, further, that this operation was not as painful as the other three must of necessity be. The patient being still seated in the chair, I flexed his elbow to a right angle and pressed it inward toward his chest; then, holding the elbow in one hand, and using the forearm as a lever, I rotated it gently and steadily outward till a distinct sense of resistance was felt. The arm was then raised with a slight inclination inward, and the hand was placed on the opposite shoulder, by which means a movement of rotation was given to the humerus. The plan was successful, and the bone slipped into place. The child was now laid on a bed, and a probe—thoroughly disinfected—was passed into the wound and the bone distinctly felt. From the direction of the probe I was afraid that the brachial artery might have been injured; after-circumstances, however, did not bear out this idea. A piece of lint spread with vaseline was placed over the wound, from which all hæmorrhage had ceased. An internal splint was applied, reaching from the axilla to the wrist, and two short pasteboard splints to the other three sides of the limb, care being taken not to press upon the axillary vein. Cotton batting was so arranged as to protect the inner condyle. Thinking that swelling and inflammation would certainly supervene, I considered it best to remove the vaseline dressing, and keep the forearm and shoulder under strict antiphlogistic treatment, which I did with lead-water and laudanum, a window being left in the splint for that purpose.

The child did well during the night. The temperature was normal, pulse 100.

On the 17th the condition of the little patient was excellent; very little inflammation: temperature normal; did not complain very much of pain.

On the 18th the old splint was removed, and a new one, made from perforated felt, applied. The lead-and-opium wash was discontinued. The wound in the forearm was dusted with calomel, and the whole covered with three thicknesses of carbolated gauze. Bandages soaked in silicate of sodium enclosed the whole.

On the 30th the patient was doing well; an angular

splint was applied, and he returned to his home, about three-fourths of a mile distant, to which he walked without assistance.

I saw him again in November last. There were no signs of deformity anywhere, except that there was about half an inch shortening. He could use each arm equally well.

Erichsen, in his *Surgery*, vol. i. p. 561, says that "in children under puberty dislocation of the head of the humerus scarcely ever occurs."

The main difficulty was found in keeping so young a patient in one position for over fifteen days, and the constant supervision and watching that were necessary. The services of the mother were worse than useless on account of her hysterical and nervous condition, and, if it had not been for the skilled attendance of one of the hospital corps, the case might have had a very different ending.

HERBERT GRAHAM,
Hospital Steward.
FORT WARREN, BOSTON, MASS.

HOSPITAL NOTES.

ASPIRATION OF KNEE-JOINT; OVARIOTOMY; HYSTERECTOMY; AND OTHER CASES.

Abstract of a Clinical Lecture delivered at the University of Michigan, Ann Arbor.

BY CHARLES B. NANCREDE, M.D.,
PROFESSOR OF SURGERY.

PROFESSOR NANCREDE stated to the class that the undersized youth shown had been the subject of necrosis of both the humerus and femur, but had recovered with a somewhat damaged knee. About two weeks ago he fell, striking the joint severely, which produced an acute synovitis. His physician, not believing in strict antisepsis, had tapped the joint with what he doubtless believed was a clean needle, but one which probably was *surgically* dirty; hence the increase of trouble and the severe pain preventing sleep, even with the free use of morphine. It was doubtful if actual suppuration was present, but tension—one of the chief factors in causing inflammation—was clearly present, and if this were relieved, provided actual suppuration of the joint and consequent commencing destruction had not been initiated, arrest of inflammation and cure would probably result.

The joint was then carefully aspirated, under full antiseptic precautions, the puncture sealed with collodion, and a firm supporting bandage with a splint applied, the lecturer stating that, later, a Martin's elastic bandage would be used if the joint did well. The fluid removed was serum with a certain amount of purulent-looking deposit, which was believed to be composed largely of young endothelial cells and migrated white corpuscles, which were yet alive, and, therefore, not *pus*, strictly speaking, which is composed chiefly of fattily degenerated, dying or dead, cells of similar origin. This condition has been variously termed catarrhal inflammation, purulent arthritis, etc., to distinguish it from suppurative arthritis, a much graver affection.[1]

The next patient, a woman in her forty-third year, presented a very large tumor, which fluctuated distinctly, and was believed by her attendant to be free from adhesions. The lecturer was also inclined to that opinion, but emphasized the impossibility of determining the fact beforehand, and that a good deal of pain had been complained of at times, which might mean a chronic peritonitis with firm adhesions.

Upon incision the whole anterior and lateral aspects of the tumor proved to be adherent, and required a tedious dissection with the fingers, knife, and scissors, and numerous ligatures before the tumor could be delivered. The whole anterior abdominal wall was adherent, as were the stomach and part of the small intestine, requiring ligation, and leaving behind some small portions of the outer part of the cyst-wall, many of the adhesions being so strong and intimate as to demand the utmost care in their treatment. The operation lasted one hour and forty minutes. Drainage was here clearly demanded, as there were probably eighteen square inches of raw, oozing peritoneal surface. The remaining ovary being slightly diseased, was also removed. [The case pursued an uneventful course, the tube being removed on the sixth day.]

Dr. Nancrede took occasion to explain the after-treatment he pursued in such cases. For the first twenty-four hours a little hot water to drink at intervals, a thirst was complained of, after this, arrowroot water, beef-tea, broths in small quantities frequently repeated; pint of tepid water injected into the rectum if much next toast and tea; finally, at the end of a week, such solid food as the patient desires. Opium is used only rarely, and then not for *pain*, but restlessness and nervous excitement, interfering with sleep; of the two evils opium is, then, the lesser. On the third or fourth day a saline laxative is administered—he preferred Seidlitz powders, one-fourth, one-half, or a whole one, as the stomach would bear it—repeated every hour or so until free purgation is induced. Should much pain with distention appear, which did not yield to turpentine enemata, purgation was instituted earlier. Quinine, digitalis, and strychnine, with stimulants, especially champagne, had kept up the heart's action in a previous case; the strychnine, given hypodermically, aiding in the expulsion of flatus. The case was unquestionably saved by the judicious use of these remedies with peptonized food, both by the mouth and rectum. Even with the vomiting of marked peritonitis, purgatives will do good if they can be retained; if not, give Epsom salts by enemata, as the lecturer had done in another case, and fed almost entirely by the rectum. Large accumulations of flatus with much liquid fæces can often be removed by the rectal tube, which had best be worn for a short time rather than frequently introduced.[1]

The lecturer, referring to operations for the radical cure of hernia, stated his belief that many of the statistics of the results of this operation were worthless, insufficient time having elapsed to demonstrate whether a cure had really been effected. Where a hernia could not be re-

[1] From the moment of aspiration all pain and inflammation ceased, sleep was normal, and prompt recovery with a good joint ensued within three weeks' time.

[1] Microscopic examination of the tumors removed from a case at a previous clinic, where secondary hæmorrhage occurred necessitating reopening of the wound, proved that they were carcinomata and undergoing mucoid softening. There was a firm fibrous envelope enabling the ligatures to hold firmly, but the soft interior portion of the pedicle was gradually forced out, thus lessening the pressure of the ligature so as to allow some vessels to ooze.

tained by a truss, the operation was always both justified and indicated, because even if the protrusion was not permanently restrained, a truss could be worn, rendering the patient a useful member of society, and no longer exposed to the risks of strangulation. When operating for this latter condition the surgeon should always aim at a radical cure, if the condition of the parts and the patient permitted.

So much diversity of opinion exists among different operators that but few universally applicable principles have been established, but to Dr. Nancrede's mind two or three facts seem to be well established, at least for inguinal hernias, viz., that the sac should be removed high up; if possible the valve-action—alleged to be normal—of the inguinal canal should be restored by drawing the postero-internal boundaries of the canal behind the antero-external and keeping them there until sufficient plastic material should be formed to hold them in contact, rather than any attempt to approximate the margins of the ring which will not adhere firmly and soon yield.

The case before the class had been operated upon by Professor Maclean, two years ago, for a very large hernia on the right side, which had remained reduced for a long period, but, as was very common, had gradually returned, though, compared to its former size, it was now a most trivial affair. On the left side was a large hernia which the lecturer operated on in the following manner:

The sac was exposed, under strict antiseptic precautions, dissected loose well up beyond the internal ring, divided, sewed up with a purse-string of stout catgut and the stump pushed above the ring. The remaining portion of the sac, except enough to form a tunica vaginalis for the testicle, was excised, and the walls of the canal approximated by a stout silver wire, after the method of Mr. John Wood, this wire being removable in two straight pieces by reversing the twists and cutting the loop on or about the tenth day. To secure most effectually a large mass of plastic material, sutures were passed through the wound-lips, but *not tied*, a drainage-tube placed *in situ*, secured by a stitch, and the wound packed with iodoform gauze. When granulation tissue had been formed in large amount the packing would be withdrawn and the wound coaptated by tightening the sutures.

The next case presented was Mrs. H., aged forty-two years, colored, the mother of one child seventeen years old, never having conceived since, and with perfectly regular menstrual periods. She had noticed seven years previously a tumor, which has now grown so as to fill completely the true pelvis and a large portion of the abdomen. For one year past it had produced steadily increasing pressure-symptoms which now bring her to Ann Arbor for operation. There was some doubt whether these hard, partly movable abdominal and apparently fixed pelvic growths were not two solid ovarian tumors, since absolutely no information could be obtained by examining the uterine cavity, the os being bound above and to the right of the symphysis pubis. The absence of uterine hæmorrhage was in favor of this view; still, the diagnosis of fibroids had been made and Professor Nancrede had come prepared to extirpate the uterus, if an exploratory incision warranted this procedure.

An incision extending nearly from the ensiform cartilage to within two inches of the pubes enabled the operator, aided by an assistant forcing up the pelvic mass through the vagina, to deliver with the utmost difficulty a large, nodulated, irregular mass of fibroids between four and five pounds in weight. The left broad ligament, including the tube, was clamped, ligated, and cut, the bladder isolated and a temporary elastic ligature applied to arrest the hæmorrhage from several large veins in the growth, lacerated in the efforts to deliver the tumors. The right ovary and tube were now removed and the wire of a Kœberle *serre-nœud* applied, the skewers passed, and the tumor and elastic ligature cut away. The operation was completed by sewing the peritoneum carefully around and to the stump, searing this with the thermo-cautery, the introduction of a drainage-tube just above the pedicle and the closure of the wound. Little if any shock was noted. The usual methods to insure cleanliness were instituted, the stump being occasionally also mopped with tincture of iodine. [From time to time the wire was tightened, the softening stump trimmed away with scissors, and the constrictor was carefully removed on the twenty-fourth day because it could no longer be tightened, had ceased to constrict, and was a constant source of annoyance to the patient. The small remains of the stump were removed piecemeal, and although the patient had at the outset a sharp attack of peritonitis, a satisfactory recovery ensued; at the end of seven weeks, only a small granulating patch being left at the point of emergence of the pedicle.]

Dr. Nancrede then presented a case of nasal deformity. He had been unable to find any record of a similar case in a hurried review of the literature of the subject, but, of course, such may exist. In reality, the condition is one where the two imperfect rings formed by the alar cartilages on either side, instead of being in contact in the median line for a considerable distance, by flattening of their opposed surfaces, have remained circular, and touch only at one spot—viz., at the anterior nasal spine, producing the effect of the so-called double-nosed pointer dog. When an infant, an attempt at cure was made by excising a wedge of tissue from the nasal tip and suturing; this has made the deformity more apparent, the elastic force of the cartilages acting like two springs to pull the tissues away from the median line.

The indications were clear enough; whether they could be effectually carried out, remained to be seen.

A tenotome was introduced along each side of the septum, and two parallel submucous divisions of the median aspect of each cartilaginous ring were made, when a suture of silkworm-gut was passed within the nostrils so as to include the partially divided cartilages and draw them together medianly: an extemporized septum compressor was then introduced with a blade in either nostril, gently held together by an elastic rubber band.

The lecturer explained that success would result slowly, if at all, and in the following manner: His submucous division of the cartilages would, to a certain extent, overcome their elastic recoil from the median line. The traumatism of the knife-cuts and the suture would result in the effusion of a considerable amount of plastic matter between the cartilages, which, after the manner of all such new tissue, would contract, tending to hold and draw more and more together the widely separated cartilages. When all that could be thus effected was secured, another operation might be attempted to raise

the depressed median cicatrix left by the former operation. A tenotome could be introduced, the scar dissected loose subcutaneously, elevated into an actual projecting ridge, and held there by harelip pins or sutures; in time the ridge would be levelled down, leaving a comparatively normal tip to the nose.

The next patient, a weaver, about thirty years of age, some two weeks ago noticed pain and swelling in the groin, which led him some days later to his physician, who said that on taxis one of two inguinal tumors apparently disappeared. The patient then had a distended abdomen, with constipation, but no vomiting; moreover, his doctor thought he recognized the characteristic gurgle of a reducing intestine. There has been slight elevation of body-heat, persistence of the bulk of the swelling, and now, within the past few days, vomiting has set in, with an increase in size of the tumor, which lies chiefly over the site of the internal abdominal ring. The inguinal canal is free from anything like a terminal protrusion, yet there is a history of an apparent partial reduction of a hernia, distended abdomen, and vomiting. The swelling is found to be both below and above Poupart's ligament, and seems to contain pus; in other words, we have a suppurating bubo.

How are the symptoms to be explained? It has been shown that every symptom of strangulation, even to apparent fæcal vomiting, can be induced by irritation of the peripheral sensory nerves of the abdominal wall and adnexa, which will arrest peristalsis. Thus, an inflamed testicle, especially when retained in the inguinal canal, an inflamed hydrocele, and more than once just such cases as this have simulated a strangulated hernia so closely that experienced surgeons have been compelled to make an exploratory incision. Opening of the abscess put a prompt end to all the peculiar symptoms.

CLINICAL CASES.

Selected from the Service of

CHARLES T. PARKES, A.M., M.D.,
PROFESSOR OF SURGERY IN THE RUSH MEDICAL COLLEGE, CHICAGO, ILL.

[Reported by A. J. OCHSNER, M.D., B.S., F.R.M.S., Chief of Surgical Clinic.]

CASE I.—Sylvia M., aged sixteen years, American school-girl. At the time of birth a small nævus was noticed opposite the infra-orbital foramen; this constantly increased in size until, at the time of the operation, she had a venous angioma covering the entire cheek, and including one-third of the upper lip, producing an extreme degree of deformity. The tumor had a thickness of one and one-half inches, and appeared through the skin covering the cheek and the mucous membrane of the lip and mouth as a somewhat irregular, purplish mass.

Operation November 22, 1889. A curved incision was carried from a point one inch below the external angle of the eye to the angle of the mouth, through the skin and fascia. Care being taken to remain outside the substance of the tumor, a thick silk suture was carried around the facial artery at a point where it crosses the lower jaw, and was tied temporarily. The upper lip was resected to the extent involved, the incision was then carried along the border of the nose to a point three-quarters of an inch below the inner angle of the eye. As much as was possible of the mucous membrane lining the mouth was saved by carefully dissecting it from the mass. All the soft tissues of the cheek had been destroyed by absorption from pressure, so that the tumor had to be dissected up from the bone. The entire flap being loosened, those portions receiving their blood-supply from the transverse facial and the infra-orbital vessels were separated and these vessels caught in hæmostatic forceps; then those portions of the skin directly involved in the angioma were cut away, and the remaining very irregular flaps dissected from the underlying angioma, and twisted about and sewed together in a manner calculated to prevent the occurrence of ectropion from cicatricial contraction, and to cover the entire surface. The remnants of the mucous membrane lining the mouth had previously been united by a continuous catgut suture. A small iodoform-gauze drain was introduced under the flap. Very little blood was lost during the operation. The wounds healed kindly, and the patient was discharged on the twentieth day after the operation. The deformity was much less marked than before the operation, and has continued to decrease. The irregularities caused by twisting the skin flaps have already disappeared to a marked extent.

CASE II.—A woman nineteen years old. Congenital angioma, as large as a pin-head when first noticed, near the centre of the upper lip. When presented for operation it was as large as a hen's egg, of a purplish color, disappeared upon pressure, but returned immediately after pressure was removed. It almost entirely covered the mouth, the tissues of the upper lip being displaced to either side and partly absorbed from pressure.

Operation December 4, 1889. Compressing the upper lip moderately on either side, by means of large forceps, an incision was made through the skin, and the tumor dissected out. The remnants of the lip were now united by sewing together the mucous membrane, the muscular layer, and the skin by means of separate rows of sutures. Perfect union took place, and the lip has already stretched to a fair length. The deformity is very slight, compared with the original one, and is constantly decreasing.

CASE III.—The patient, a woman of twenty-six years, had a small nævus on the upper lip, a little to the left of the centre, which constantly enlarged, notwithstanding treatment with electrolysis, until it became a purplish mass as large as a hen's egg, causing the upper lip to extend far below the under and up on the left cheek.

Operation January 15, 1890. The tumor was carefully dissected out; the hæmorrhage was very slight, being controlled mainly by pressure; the remnants of the lip were united by three rows of sutures, as in the previous case. The wound united kindly, and the lip is assuming a very natural appearance; the scars are slight, and the deformity is decreasing.

In these cases the hæmorrhage was slight, because the dissection was made outside of the tumor, for it is only when the tumor is cut into that there is any considerable loss of blood. In case of bleeding from the tumor, it is most easily controlled by lifting the mass from its base, and grasping it between the finger and thumb. After such operations the deformity is usually much less than anticipated, because the tumor displaces rather than destroys the surrounding tissues.

In all these cases the dressings consisted of iodoform gauze and borated cotton.

CASE IV.—The patient was a Scandinavian woman, forty-eight years old, of good habits. For twenty years she has had a right inguinal hernia, usually retainable by means of a truss; seventy-two hours previous to her admission it had become incarcerated, and all attempts at reduction, made by the patient, were in vain.

Operation November 17, 1889. Upon opening the sac the intestines were found to be black with small whitish spots of lymph here and there. The peritoneal covering of the intestine, however, still had its shining appearance, and the intestines were returned into the peritoneal cavity after enlarging the ring by means of a probe-pointed knife, guided by the finger. The sac was so nearly necrotic that it was peeled out without effort or bleeding. It was cut off a little outside of the ring, and the ring and canal were packed with iodoform gauze, and iodoform gauze and borated cotton dressing were applied. The patient's temperature fell from 103° to 99.5° during the next twenty-four hours, and much flatus was passed. On the second day there were three free evacuations of the bowels. The patient continued to progress, and the wound remained aseptic, although there was some serous discharge from the necrotic surfaces. On the tenth day the patient had some pain, which subsided after taking some hot brandy. On the twelfth day the discharge from the wound, which had been kept open by the iodoform gauze, had a slightly fæcal odor. For one week there was some fæcal discharge, but the wound again became clean, the amount of packing was decreased, and nine weeks after the operation the wound was entirely healed. The canal is now filled with a solid mass of connective tissue, and the patient's bowels act normally. The patient's life was undoubtedly saved by the use of iodoform packing, which permitted the discharge from the break in the intestine to come out, and so preventing the occurrence of perforation peritonitis by keeping the external wound wide open. The wound in the intestine healed rapidly, preventing the annoyance of a fæcal fistula.

CASE V.—The patient, a woman, twenty-nine years old, had suffered for two years from left inguinal hernia; the pain was very severe, and excited nausea when the hernia was down. It was never very difficult to reduce the hernia, but always quite painful.

Operation January 21, 1890. The sac contained the ovary and a portion of the Fallopian, distended to three-fourths of an inch in diameter and adherent to the inner margin of the ring. The tube and ovarian artery were ligated by transfixion with a double ligature, and the ovary and enlarged portion of the tube were removed; the stump was returned into the abdominal cavity; the sac dissected out, ligated, and cut away, and the ring and canal closed by continuous catgut sutures. The wound healed primarily, there being nothing abnormal in the recovery, excepting a slight abscess in one of the stitches through the skin. There is a firm mass in the canal, and no protrusion upon coughing or straining.

CASE VI.—Patient was a married woman, twenty-eight years old. An irreducible femoral hernia was induced by patient making a misstep. During the first twenty-four hours several fruitless attempts at reduction by taxis were made by the attending physician. On January 23d, twenty-four hours after the occurrence of the accident, herniotomy was performed. The sac was black, and the hernial fluid dark-colored and of extremely bad odor. The hernia was found to consist of the elongated and perforated vermiform appendix, which had become necrotic except at its base. An enterolith was found free in the cavity of the sac, having escaped through the opening in the appendix. The appendix was tied at its base with silk, and cut off, and its cavity thoroughly cauterized with strong carbolic acid; the sac was dissected out, and cut off without tying, and the wound was packed with iodoform gauze. On the fifth day there was a distinct fæcal odor in the packing; this odor lasted four days. The wound healed by granulation from the bottom, being entirely closed on February 23d. There was, at no time after the operation, any rise in temperature, or any other symptom indicating the gravity of the conditions present at the time of the operation. Here, again, the free packing of the wound with iodoform gauze was a source of safety to the patient.

CASE VII.—The patient is a man, twenty-five years old, carpenter by trade. Four months ago, while lifting a heavy weight, he felt a severe pain in the left inguinal region, and directly after noticed a tumor in this region, which gave rise to much pain and some nausea. The attending physician diagnosed an omental hernia, which he reduced in part by taxis, getting the characteristic gurgling sound, which was also heard by the patient. Physician and patient state that the tumor was twice its present size before the use of taxis. The remaining portion of the tumor continued to be painful, became slightly larger, and somewhat inflamed, the skin being red over it. At the time of the operation, January 20, 1890, the tumor had the appearance of a bubo. The incision over the inguinal canal exposed an infected lymphatic gland as large as a walnut.

The abdominal ring was large, but no hernial sac could be found. The wound was packed with iodoform gauze, and healed rapidly by granulation.

The patient denies the possibility of specific infection.

CASE VIII.—The patient, a man, twenty-four years old, whose right testicle has never descended into the scrotum, has experienced much difficulty in retaining a congenital hernia of the right side. When it is down there is severe sickening pain, which is readily relieved by reducing the hernia.

Herniotomy February 18, 1890. The sac was found empty at first, but, upon straining, the testicle, about half the normal size, came through the ring. It was impossible to bring it down into the scrotum. Ligation by transfixion with double silk ligature, removal of testicle, and returning the stump into the ring were practised. The canal was closed by three rows of continuous catgut sutures. By February 24th the wound had united throughout.

CASE IX.—Mrs. C., housewife, forty-six years old. For eleven years this patient has been treated in vain for lupus of the face. As a result of the irritation, there is now a distinctly marked epithelioma implicating an oval surface four by six inches, including one-fifth of the ear and extending in front above the ear over the side of the face and scalp.

Operation November 4, 1889. Removal of skin and fascia one-third of an inch beyond all parts of the disease, including the diseased parts of the ear. After ligating the large vessels, the entire surface and the margins

were thoroughly cauterized with the Paquelin cautery. An iodoform gauze and borated cotton dressing was applied and allowed to remain for a week, then a wet two per cent. carbolic acid dressing was applied and renewed every third day to stimulate the exfoliation of the eschar. After three weeks the entire surface was covered with fine healthy granulations. These were curetted away and the surface covered with long shavings of skin, after Thiersch's method; these were covered with strips of Lister protective silk, borated cotton, wet with 6 to 1000 solution of table salt, over this a piece of gutta-percha tissue was placed, and over all a large piece of cotton and a roller bandage. This dressing was changed every second day for ten days.

The wound on the ear was freshened and united with the part attached to the side of the head, causing it to look quite natural and only a little smaller than the one on the other side.

After two weeks the entire surface was smoothly healed, and by wearing a wig, the apparent deformity was very slight. In quite a number of cases where we have grafted skin, after Thiersch's method, on defects caused by the removal of tumors the results have been very satisfactory. These cases will be published in full at a later date.

Case X.—Six months ago the patient, a man, forty years old, had his face severely burned by the explosion of natural gas in a shaft. When healing was completed there was ectropion of both lids of each eye, so that what was left of the eyebrows and eyelashes was almost completely united.

Operation November 30, 1889. An incision was made parallel to the margin of the lids and one-eighth of an inch away from them, extending quite through all of the cicatricial tissues and into the subcutaneous connective tissue. The margins of the upper and lower lids were now united by rows of continuous sutures of fine silk. The bleeding was controlled by pressure. The entire surface equal to the area of the skin covering normal eyelids was covered with grafts, according to Thiersch's method, care being taken to press the skin into the depressions caused by the incisions. Salt water compress was applied and changed every other day for ten days; at the end of two weeks the lids were liberated and the patient advised to use his eyes carefully. The lids were well covered and the eyes well protected, which condition has continued to improve since the operation.

Case XI.—Mr. D., sixty-five years old. Patient had suffered for several years from increasing ectropion of lower lids. Conjunctivæ highly inflamed, tears constantly flowing down over the cheek.

Operation December 8, 1889. An incision was made parallel to the margin of the lower lid and one-fifth of an inch from it, extending through the skin and into the subcutaneous connective tissue. The lower lids were then fastened over the upper lids by means of six stitches held on the forehead by rubber adhesive straps for the purpose of immobilization. The raw surface thus formed was covered with skin grafted after Thiersch's method. After ten days the lids were released, the grafts had "taken" throughout and the irritation on the conjunctiva had begun to subside. Six weeks later the lids were quite normal, and they have continued so to the present date, ten weeks after the operation.

MEDICAL PROGRESS.

Parasiticide Ointment.—According to the *Journal of Cutaneous and Genito-Urinary Diseases*, the following is useful, both in skin affections depending upon pediculi as well as in those due to the vegetable parasites:

R.—Salicylic acid	. . .	45 grains.
Borax	. . .	15 "
Balsam of Peru	. . .	30 "
Vaseline	. . .	5 drachms
Ethereal essence of anise	.	5 drops
Essence of bergamot	.	20 " —M.

Prescription for Pruritus.—The following prescription for pruritus of the anus or vulva is quoted in the *Buffalo Medical and Surgical Journal:*

R.—Sodium hyposulphite	. .	3½ drachms
Carbolic acid	. . .	30 grains.
Glycerin	. . .	2 drachms.
Water	. . .	3½ ounces.—M.

Nutritive Enema.—According to the *Satellite*, Jaccoud recommends a nutritive enema composed as follows:

R.—Beef tea	. . .	8 ounces.
Wine	. . .	4 "
Yolks of two eggs.		
Dry pepsin	. . .	1 to 5 drachms.

Tincture of Capsicum in the Pneumonia of Drunkards.—Dr. Netschaeff, in the *Vratch*, highly recommends the tincture of capsicum in the treatment of pneumonia occurring in alcoholics. He uses the tincture of capsicum annuum according to the following formula:

R.—Tincture of capsicum	.	1 drachm
Water	. . .	5½ ounces.
Syrup	. . .	5 drachms.—M.

One teaspoonful every two or three hours.

The pure tincture in doses of 20 drops, well diluted, may also be employed. If in spite of these doses the heart becomes weaker and the nervous symptoms more pronounced, the dose should be increased, as no harm will follow the administration of very large amounts.

The author thinks that the remedy causes the disappearance of delirium, modifies the character of the pneumonia, increases the appetite and promotes sleep. —*Wiener medizinische Presse*, February 23, 1890.

The Treatment of Scabies with Petroleum.—Dr. Bourgeois, in the *Revue Générale de Clinique et de Thérapeutique*, gives the following details of the treatment of scabies with petroleum, which he believes is one of the most efficient parasiticides: The first day he orders, just before the patient retires, inunctions of petroleum over the whole surface of the body, except the head, rubbing more particularly the affected surfaces. The shirt is then resumed and the patient put to bed. The next morning the greasy substance is washed off with warm water and white soap. The linen is changed, and the patient goes about his usual occupation. At night, before retiring, a new application of petroleum is made, as before, and the following morning the same procedure to remove

the oil. Ordinarily, after the second day the itching is completely relieved; but, as a measure of security, it is well to make a third application, after which the patient may be considered completely cured.

The author claims that this treatment is entirely innocuous and free from pain. It would seem to be quite efficacious, since in fourteen cases there were fourteen complete cures, without the necessity of disinfecting the garments.—*Journal of Cutaneous and Genito-Urinary Diseases*, March, 1890.

The Cause and Treatment of Chlorosis.—According to the Paris correspondent of the *British Medical Journal*, M. DUCLOS believes with Sir Andrew Clark, that chlorosis is a fæcal auto-intoxication, which should be treated by purging, prolonged until the intestine is completely freed from all the hardened and decomposed fæcal matters. He recommends a vegetable rather than meat diet. When constipation is not very marked the affection results from the great activity of putrid decomposition, and should be treated with carbonate of soda combined with carbonate of lime, magnesia, and charcoal. Iron is beneficial because it forms an iron sulphide with the hydrosulphuric acid in the intestine. Hyposulphite of sodium has been of use in checking fæcal fermentation; naphthol might serve the same purpose.

The Analgesic Properties of Exalgine.—DR. THOMAS R. FRASER has been conducting a series of observations upon the analgesic effects of exalgine (*methylacetanilide*) in the Edinburgh Royal Infirmary. The studies were with sixteen diseases in twenty-one patients, and, among other affections, included facial neuralgia, sciatica, locomotor ataxia, rheumatic synovitis, abdominal cancer, and aortic aneurism. The doses prescribed were small, one, two, or four grains, and the largest amount given in twenty-four hours was fourteen grains. No disagreeable symptoms were produced in any of the patients. An analysis of his lecture (*British Medical Journal*, February 15, 1890) shows that eighty-eight separate administrations of the drug were made and that in sixty-seven pain was relieved. The condition of some of the patients, however, was such that relief could not be expected without general narcotism. The best results were obtained in the various forms of neuralgia where fifty-two administrations gave relief forty-eight times. Dr. Fraser concludes his lecture by stating that the analgesic effect of exalgine is not a very powerful one, but that it has the enormous advantage of being free from the inconveniences of other pain-subduing agents and from the dangers of the more powerful of such agents.

GAUDINAU (*Therapeutische Monatshefte*, February, 1890) also writes in praise of the analgesic properties of exalgine, and states that a single dose of from four to eight grains causes the pain of neuralgia and of rheumatic synovitis to disappear within an hour. The only unfavorable effects observed are occasionally tinnitus aurium and a feeling of intoxication. The author prescribes the drug as follows:

R.—Exalgine	37 grains.
Alcohol	3½ drachms.
Syrup	1 ounce.
Water	6 ounces.—Mix.

One tablespoonful as required.

At the recent International Congress of Therapeutics held in Paris there were a few dissenting voices, but the majority of speakers upon exalgine considered it a valuable analgesic. Mr. Bardet stated that much of the so-called exalgine is in reality a different and inert substance. M. Dujardin-Beaumetz believed that it had undoubted analgesic properties, but that on the whole it was inferior to antipyrine. He had also found that if continued long or given in large doses disagreeable though harmless giddiness was often produced.

Collodion in Atony of the Tympanic Membrane.—DR. KELLAR, of Cologne, uses collodion in the treatment of deafness due to relaxation of the tympanic membrane. After the middle ear is inflated the patient's head is strongly inclined toward the healthy side, an aural speculum is introduced, and the collodion dropped into the auditory canal. The excess of collodion is immediately absorbed with cotton. An examination is then made, and if the membrane is not completely covered the procedure is repeated. The author claims that the effects are excellent.—*Wiener medizinische Presse*, February 23, 1890.

Mussanin; a New Anthelmintic.—In the bark of an Abyssinian tree, the Acacia Anthelmintica, THIEL has discovered a new anthelmintic which he terms *mussanin*. The anthelmintic properties of the drug are said to be more powerful than those of koussu and the taste is much more agreeable. The powdered bark may be given in doses of from one to two ounces, or it may be administered in the form of an infusion. The author considers that the drug is destined to assume an important position in therapeutics.—*Wiener medizinische Presse*, February 23, 1890.

Prescription for Pityriasis Capitis.—DR. M. D. STERN recommends the following ointment for pityriasis capitis:

R.—Ammoniated mercury	2½ drachms.
Green soap	10 "
Lanolin	1½ ounces.—M.

—*Journal de Médecine de Paris*, February 23, 1890.

Orexin.—The Berlin correspondent of the *Provincial Medical Journal* writes as follows on the use of orexin, a remedy recently introduced, which is said to increase the appetite and aid digestion. Clinically the drug has been tried in cases of loss of appetite following operations and accompanying phthisis, affections of the stomach, and various other diseases, such as albuminuria, anæmia, and dyspepsia. The results of the use of orexin hydrochlorate in thirty six cases were in accord with the observations on normal individuals; the appetite was stimulated and the digestive powers increased. The amount administered never exceeded eight grains at a dose nor twenty-four grains daily, though these doses produced no unpleasant symptoms. It was found that one, or at most two doses daily were sufficient to cause the desired effects. It was at first prescribed in wafers, but owing to its bitter taste and the production of a burning sensation in the mouth and throat, gelatin-coated pills were found to be preferable. On account of the irritating properties of the drug large quantities of fluid should be swallowed after each dose.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MARCH 22, 1890.

THE RELATIONS BETWEEN THE BACILLUS COLI COMMUNIS AND THE BACILLUS OF EBERTH.

PROBABLY the bacteriological question of greatest practical interest is whether an organism may be benign in one locality and malignant in another; or, to state it differently, whether the property of infection is an adventitious one depending upon the soil in which the organism grows, or inherent in its substance. An attempt to solve this problem, in so far as it relates to the typhoid bacillus, has just been made by RODET and ROUX (*Comptes Rendus Hebdomadaires des Séances de la Société de Biologie*, February 21, 1890), whose researches have led them to conclude that the bacillus of Eberth is nothing more than a modification of the bacillus coli communis.

The facts upon which they base this opinion are of two kinds. In the first place, they made cultures of the blood of the spleen and of the fæcal matters of two typhoid patients, and found that the former produced nothing but the bacillus of Eberth, and the latter little else than the bacillus coli communis —the bacillus of Esherich.

In the second place, according to Rodet and Roux, the optical points of resemblance between the two bacilli are greater than those of difference, and are such as to warrant the belief that the one is a modification of the other. Carefully conducted cultures in gelatin, potato, and bouillon, exhibit similar macroscopic appearances, while the limits of temperature within which the two organisms can be cultivated are almost identical, being somewhat higher (46.5° C.) in the case of the bacillus coli than in that of Eberth's bacillus (45°).

Under the microscope the differences are more marked, the bacilli coli being of almost uniform length, homogeneous in structure, slightly mobile, and staining readily, while the bacilli of Eberth are of unequal length and thickness, are more mobile and stain less readily than the bacilli coli. The structure of their protoplasm also is evidently not homogeneous.

If, however, the bacillus coli be cultivated at a temperature of 44° to 46° C. it undergoes such changes as to cause it to bear a remarkable resemblance to the typhoid bacillus. The rods become of unequal length; their protoplasm ceases to be homogeneous, and presents a series of readily staining condensations, separated by clear intervals; in a word, the result of numerous observations of the sort is to show that while the type of Eberth's bacillus is relatively fixed, that of the bacillus coli is remarkably unstable, and, by a series of transitions, approaches and even becomes identical with the former.

The typhoid bacillus of Eberth is, according to the authors quoted, the bacillus coli in a state of degeneration. This is shown by the fact that the former is less able to resist heat than the latter, Eberth's bacillus being destroyed by a temperature (80° C.) which is supported by the bacilli coli. This is far from saying that the bacillus which causes enteric fever is in a state of degeneration at the time of infection. The bacillus coli becomes virulent without any notable change in its appearances and other characters, and it is in the interior of the organism, especially in the spleen, that it assumes the features of Eberth's bacillus. The latter are the result of the destructive forces of the body. The practical conclusions from these researches are twofold:

1. Water contaminated with fæcal matter, not necessarily typhoidal, may give rise to enteric fever.

2. The tolerance of the organism for the bacillus coli shows that the latter acquires its virulent features outside of the body.

It is to be hoped that the experiments of Rodet and Roux will be thoroughly investigated. Certainly, none more practical could engage the atten-

tion of bacteriologists. If confirmed, the term pythogenic fever, introduced many years ago by Murchison, may yet be generally accepted as the proper one for the disease which is now somewhat vaguely styled typhoid or enteric fever.

REVIEWS.

Monthly Nursing. By A. Worcester, A.M., M.D. Second edition. 12mo., pp. 250. New York: D. Appleton & Co., 1890.

The important position assumed by skilled nursing during the past few years is well shown by the number of text-books on the subject which have appeared. Unfortunately, many of these books are more fitted for the medical student than the student nurse, containing much that the latter neither can nor need understand. Such cannot be said of the volume before us. Written in the attractive style of an easy conversational lecture, it makes no attempt to teach more obstetrics than is absolutely required by a competent nurse in dealing with the emergencies and trying circumstances with which she is sure to meet. The author has also "tried to tell what kind of service the physician and the patient have the right to expect from the monthly nurse," and, we may add, tried with entire success. For these reasons the book is of more value to the nurse, and less to the physician, than any with which we are familiar, though its usefulness could have been still more increased by the addition of a few wood-cuts, a more copious index, and some system of convenient reference.

Hand-book of Materia Medica and Therapeutics. By Samuel O. L. Potter, M.A., M.D. Second edition. Revised and enlarged. Philadelphia: P. Blakiston, Son & Co., 1890.

Although Potter's *Therapeutics* has been but a short time before the medical profession, there can be little doubt that it has come to be regarded as one of the works to which American medicine can point with pride. Its chief fault seems to us to lie in the endeavor of its author to place too much minute information on a comparatively small number of pages; that is to say, the portion of the book which is devoted to materia medica and therapeutics might, without disadvantage, fill the entire volume. The discussion of part third, known as Special Therapeutics, is certainly of sufficient importance, if mentioned at all, to deserve more pages than it now covers. Notwithstanding the defects, which are chiefly those of omission, we think the book is one which may be recommended both to students and practitioners when in search of therapeutical knowledge. At the same time we believe that the arrangement of differential diagnosis is one which of necessity has to be so superficial as to permit of error in the hands of one whose information depended almost entirely upon this source. As one turns the pages he is struck by the great number of subjects which are noticed. Patent medicines find space for analyses of their contents, and very properly precede the portion of the work which discusses the treatment of poisoning. One advantage of the book is that it mentions drugs which are not officinal, but which are frequently used in medicine, at least in certain parts of the United States. In the appendix, a list of Latin words and phrases used in writing prescriptions is given, and a very good general index, not divided into the consideration of drugs and diseases, ends the volume.

The publishers have, however, increased the diameter of the work to a considerable extent by the addition of a goodly number of advertising pages, which to the book purchaser may be considered as an advantage or a disadvantage directly measurable by the capacity of his pocketbook.

A Handbook of Obstetrical Nursing. By Anna M. Fullerton, M.D. 12mo., pp. 214. Philadelphia: P. Blakiston, Son & Co., 1890.

This little book is one of the best which has so far appeared upon the subject of obstetric nursing. Though not claiming originality, it shows an intimate acquaintance with the requirements of a nurse, and leaves no doubt in the mind of the reader that the author is experienced in the management of labor and the puerperal state. Careful and minute instructions are given for the preparation of the patient and her surroundings. The accidents which may happen in the absence of the physician are described, and the duties of the nurse in such emergencies are clearly explained.

Particularly detailed are the instructions upon the use and preparation of the various antiseptics used in obstetric practice, creolin apparently being the antiseptic preferred by the author. The various devices for the sterilization of milk, most of which are unnecessarily complicated, are also described at length. Altogether, the book is very satisfactory, and one that we can recommend both to the student of nursing and of obstetrics.

Electricity in the Diseases of Women, with Special Reference to the Application of Strong Currents. By G. Betton Massey, M.D. 12mo., pp. 210. Philadelphia and London: F. A. Davis, 1889.

An inspection of this book will show that it is a notable production, not only as the first systematic exposition of a new and conservative method of treating many of the diseases of women, but also as the first book on medical electricity based on modern ideas of currents and employing the terms that belong essentially to the era of the dynamo and the electric light. This is shown by the absence of the obsolete theories and wearisome explanations that are usually found in electro-therapeutic works, the reader's attention being immediately directed to a consideration of the currents themselves as therapeutic entities rather than to the batteries that produce them, although enough space is given to apparatus and similar details to indicate the author's choice, and the proper method of handling them.

A special chapter is given to the physical characteristics of each current, illustrated by detailed experiments.

There certainly can be no better way of mastering the intricacies of volts, ohms, milliampères, than an actual performance of these experiments, preferably upon one's self, if possible, or even upon a subject.

Following this practical consideration of currents, and their management, which, indeed, is the most valuable

part of the book to the beginner, a chapter each is given to intra-uterine, galvano-chemical cauterization; electro-puncture; vaginal applications; and general percutaneous application. In each of these, explicit and exact directions are given.

The therapeutical portion is ushered in by Chapter XI., devoted to the electrical treatment of fibroid tumors of the uterus. This is, of course, an important feature of the work, and much space is given to detailed notes of cases rather than to the glittering generalities that some writers think sufficient to carry conviction. Here, as elsewhere, the author confines himself to his personal experience. The intra-uterine method is mainly relied upon, puncture being but seldom advised. An aseptic, pliant electrode capable of being insulated beyond the os, and the use of soaped absorbent cotton pads, instead of clay, for currents under 100 milliampères, are the main departures recommended from the oft-described method of Apostoli.

Chapter XVII. is a concise statement of the claims of electricity in the treatment of extra-uterine pregnancy. Fœticide by the faradic current is recommended in cases diagnosed before rupture, followed by the galvanic current for the promotion of absorption. Both currents are to be applied without puncture, the sac being merely included between an electrode in the vagina and one on the abdomen. Chapter XVIII. deals with the treatment of amenorrhœa and hydrosalpinx.

In the final chapters of the work devoted to the contra-indications and limitations to the use of strong currents, any attempts at electrical treatment are condemned in *cystic ovarian tumors* and in *papillomatous tumors* of the broad ligament, the author basing his opinion mainly both upon the history of published attempts and the want of a rational basis for such treatment. The opening paragraph of this chapter is worth quotation:

"The voice of authority cannot be too early raised against the indiscriminate and careless employment of the powerful agency treated of in these pages. It is in the nature of things that a power for good, when unharnessed, becomes an engine of evil in proportion to its potentiality; hence an operator who cannot bring a calm and unbiassed judgment as well as electrical knowledge and skill to this work had best leave it alone."

We have endeavored to present in condensed form Dr. Massey's views as expressed in his book. In our opinion electricity, in the treatment of certain diseases of women, has come to stay.

Du Sang et de ses Alterations Anatomiques, par Georges Hayem. 8vo., pp. 1023. Paris: G. Masson, 1889.

This book, written by one who has devoted a very large amount of time and study to the physiology and pathology of the blood, has been received, both in France and in this country, by those who are fortunate enough to read French, with a great deal of interest, and has already obtained for itself a large amount of praise from those who are best qualified to judge of its value. Dealing as it does in the most thorough manner with everything that can possibly appertain to the subject, and being illustrated by a very large number of colored drawings, it affords by far the best book of reference in the study of this, the most important tissue of our bodies.

During the past few years so much attention has been paid by clinicians and pathologists to the changes which take place in the blood of human beings suffering from various diseased conditions that Dr. Hayem has found, in addition to his own experience, a very large amount of interesting material which he has embodied in his book, leaving out, with unusually good foresight, all studies which have seemed in any way imperfect or unworthy of mention.

Unfortunately, books devoted to the study of comparatively limited portions of the body seldom possess a sufficient popularity to warrant their translation into the English language, but we think that in this instance the profession in America and England would find so much of practical utility in the book before us as to justify its translation. This is particularly the case owing to the fact that so great an amount of information is contained in its pages, the result being that physicians in all the branches of medicine would find matters of interest. The physiologist will find careful statements regarding the condition of the blood and the tests for the isolation of the various crystals and their bodies. The physician will find information as to the manner in which he is to seek for variations in the number of the various corpuscles and in the quantity of the hæmoglobin, while the pathologist will also obtain valuable additions to his knowledge in regard to the abnormal changes which may take place. Dr. Hayem's book is certainly the best one which has ever appeared upon this subject, and its reliability is attested by the well-known investigations and studies of its author heretofore given to the profession.

Saunders's Question Compends: Essentials of Obstetrics Arranged in the Form of Questions and Answers. By William Easterly Ashton, M.D. 12mo., pp. 220. Philadelphia: W. B. Saunders, 1890.

This book, which has already reached its fourth thousand, has been written by the Demonstrator of Clinical Obstetrics in Jefferson Medical College, and considering the fact that its size has, of necessity, to be a limited one, Dr. Ashton has certainly placed between its covers a large amount of information. While the use of questions and answers may not seem to the busy practitioner to be of any particular value, the experience of the medical student teaches him that this arrangement is one which is the most apt to impress upon his memory the important points for the examination room and for his early practice. Dr. Ashton's book certainly has proved of sufficient value to make for itself a large sale within a short time, and we think that those students who, by reason of the limited development of their cortex, are forced to buy this variety of literature will find the book one of the best that can be obtained.

Physicians' Leisure Library: Diabetes. By A. H. Smith, M.D. 12mo., pp. 74. Detroit: George S. Davis, 1889.

This little book contains within a short space a fairly good *résumé* of the important subject of which it treats, and a very large portion of it is very properly devoted to the prevention and treatment of this troublesome dis-

ease. It is stated in the preface that a large amount of the information which it contains has been obtained from the articles of Dr. Tyson in Pepper's *System of Medicine*, and in the *Annual of the Universal Medical Sciences* for 1888 and 1889.

The advantage of combining a large amount of information in a small space has been recognized to such a degree that the physician in a comparatively short time may obtain a very good idea of the condition with which the book deals without an undue amount of mental effort.

THE CURE OF CROOKED AND OTHERWISE DEFORMED NOSES. By JOHN B. ROBERTS, A.M., M.D. 12mo., pp. 24. Philadelphia: P. Blakiston, Son & Co.

THE author of this little brochure of twenty-four pages frankly states, in his introductory remarks, that the performance of the operations described may be "a source of revenue to the operator." This being often a very important branch of medical science, the volume will, doubtless, have many readers. As the subject-matter compares very favorably with chapters on this topic in standard surgical text-books, it will probably be welcomed by the general surgeon. The teachings of rhinological specialists are, however, much more moderate: the extreme measures advocated by Dr. Roberts having been almost wholly abandoned by them some years ago.

TEXT-BOOK OF MEDICAL CHEMISTRY. By ELIAS H. BARTLEY, B.S., M.D. Second edition, revised and enlarged. 12mo., pp. 423. Philadelphia: P. Blakiston, Son & Co., 1890.

THIS book presents in a convenient and readily accessible form, much of the chemical knowledge required by physician and pharmacist. Part I. is devoted to elementary physics, and contains an excellent and instructive section upon the theory and nomenclature of electricity, concerning which, it is to be feared, most physicians have had but imperfect instruction. Theoretical chemistry, so appalling with its complex formulæ to the student at the beginning of his studies, is simply yet thoroughly explained in Part II. In Parts III. and IV., inorganic and organic chemistry are treated of in a somewhat conventional manner, with here and there detailed considerations of elements and compounds of direct interest to the physician. For example, under the head of hydrogen and oxygen, the methods of water analysis and various tests for impurities are described, as well as the composition of many of the mineral waters.

The section on poisons is the least satisfactory of any, as some of the antidotes mentioned are not antidotal to the poisons for which they are advised. Alkaline carbonates, baking soda, and soap, recommended here in cases of oxalic acid poisoning, should not be used, as the oxalates of sodium and of potassium are themselves toxic. In the treatment of carbolic acid poisoning, oil, emetics, and the stomach-pump are advised, no mention being made of the soluble sulphates, the true antidotes to this acid. Moreover, emetics will seldom, if ever, act, owing to the complete anæsthetization of the sensory nerves of the stomach. With these rather unfortunate exceptions, the volume is an excellent text-book, and one for which there is doubtless a place.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Section on Surgery.

ROBERT ABBE, M.D., IN THE CHAIR.

Stated Meeting, February 10, 1890.

The meeting was devoted to a discussion of the subject of the treatment of fracture of the patella, and interesting cases illustrating the good results obtained by the operative method were presented by Drs. Abbe, Fluhrer, and Willy Meyer.

DR. W. T. BULL read a paper on the

RESULTS OF THE TREATMENT OF FRACTURED PATELLA WITHOUT OPERATION,

and illustrated his paper by presenting a number of cases which had been treated in this manner. Many of them had received their fractures eight or ten years before, and although representing active occupations, such as firemen, policemen, and truck-drivers, they were able to attend to their duties very well.

Dr. Bull said that before the times of antiseptic surgery bony union was so rare that surgeons usually contented themselves in endeavoring to obtain short ligamentous union; but with the advent of modern methods bony union was eagerly sought after. Much was expected from these new methods, but they were soon found to be dangerous, and rapidly fell into disfavor.

His paper was based upon the histories of twenty-two cases of fractured patella which had been treated without operation, and had been followed for periods varying from one year and nine months to thirteen years after the injury. There were sixteen cases of primary fracture and six of refracture; but as the latter class cannot be expected to yield such good functional results as the former, they were not considered. The results of treatment were classified under three heads, viz.: (1) Functionally perfect—ten cases, in which flexion and extension of the limb have been complete and strong, the ligament firm, and little or no atrophy of thigh; (2) good—four cases, in which flexion and extension were imperfect, but the joint was sufficiently useful to satisfy the demands of the patient's occupation, and only showing weakness after unusual exertion; and (3) bad—two cases, in which there was no power of extension, and the patients were compelled to wear supports, or to walk with a cane. Three-fourths of these patients were between the ages of twenty and forty years, and their occupations were sufficiently laborious to test the efficacy of the treatment. Bony union was obtained in one instance, and it is noted in two others that there was no appreciable separation of the fragments; while in the remaining cases the average length of the ligament was nine-tenths of an inch. This corresponds very well with the statement usually made that the length of a useful ligament varies between one-half inch and one inch. In one case the ligament was observed to shorten during a period of some years, owing to the formation of bone in the ligament.

Out of six cases of refracture, three occurred within two months after being discharged from the hospital, and in one case the lower fragment was fractured while the ligamentous union remained intact. The results in two

cases out of this series were surprisingly good, and in the remaining four there was deficient extension, three having long ligaments.

Neither the age of the patient nor the character of the injury seemed to influence the result. From the first series good results were obtained in eight out of ten cases by the use of simple retentive apparatus, provided no accident endangered the newly formed ligament. As refractures were considered accidents, they should be included with those giving a less favorable although still a very good percentage—seventy-three per cent.

If the cases were seen soon after the injury the knee was slightly elevated, equable pressure was made by means of cotton compresses and snug bandaging, and, after an average period of five days, the limb was elevated and a gypsum bandage applied, the fragments being approximated by loops of plaster. It is possible, by proper application of a figure-of-eight bandage, not only to tilt the fragments but to separate their margins. After the effusion has subsided, there is no tendency to drawing up of the fragments. After the gypsum bandage has "set," the patient is allowed to sit up. Six or eight weeks later this bandage is removed and a posterior splint, or the posterior half of the gypsum dressing, is bandaged to the limb during the day. At this period vigorous shampooing and the use of electricity should be begun. About the third month extension is usually good, although flexion is only possible to about forty-five degrees. The patient may now be allowed a cane, but the use of knee-caps should be discouraged, and passive motion is rarely advised. The patient is to make daily efforts to bend the knee slightly, the foot being upon the floor. There is no liability to accident by this method.

Many surgeons are still opposed to the use of plaster-of-Paris, thinking that it causes atrophy and interferes seriously with the circulation; but the use of plaster is not recommended by Dr. Bull until the swelling has subsided, and cotton is always applied underneath.

It will be seen that the total time of treatment is about six months; but the patient is confined during six weeks and allowed only moderate movement for six weeks more. The time of treatment cannot be advantageously shortened. If the ligament and joint functions begin to weaken, it is advisable to resort to wiring the bone, and the operation is easier at this time than subsequently when the fragments are more widely separated. Cases of refracture should be treated upon the expectant plan until it is apparent what the results will be.

Malgaigne's hooks have been employed both with and without antiseptic methods, and Treves speaks favorably of them; but it does not seem that there is anything gained by their use. All such measures aim to secure bony union, but they are both risky and meddlesome.

In the discussion that followed, Dr. L. A. Stimson said that refracture was common after all methods of treatment, and we were not justified in claiming bony union for any case unless an ocular demonstration of its existence by a section through the parts had been made. The most we could claim is an absence of independent mobility. In an extensive review of the literature of the subject, he had been impressed with the widespread opposition to arthrotomy and metallic suture. During the past fourteen months he had treated twenty-four cases by a new method of subcutaneous suture, which had been suggested to him by his house-surgeon, Dr. Clark. The operation had generally been performed under cocaine anæsthesia, the cocaine being introduced at four points, two above and two below the fracture and a little to one side of the median line. Incisions half an inch long were made at these four points, and a stout silk suture introduced with a large half-curved Hagedorn needle. The ligature was first passed through the ligamentum patellæ, reëntered again at the point of exit and passed upward in front of the fragment and brought out at the upper opening on the same side. It is again reëntered and passed close to the patella, catching the substance of the quadriceps; and in the same manner carried back to the starting-point. By means of tenacula in the quadriceps and patellar tendons, the fragments are approximated and held firmly until the suture is drawn tight, tied, and the ends cut off. As the punctures permit an escape of blood from the fracture, and open a communication with the joint, the operation is not entirely devoid of risk; but so far there has been no suppuration within the joint. An antiseptic dressing is applied, and the limb placed on a posterior splint for one week, when the incisions are found healed. Plaster-of-Paris can then be substituted and allowed to remain on for one month. When a second plaster splint is required, it will only be necessary to wear it during the daytime. The results so far have not been very favorable, but there are reasons for believing that these can be much improved.

Dr. Charles McBurney had always been opposed to operations for fractured patella except when the fracture was compound, as he considered it quite dangerous, and the functional results obtained by the non-operative method were too good to justify the taking of such risks. He had been able to secure excellent approximation by means of plaster extending over the quadriceps tendon and down the leg, and covered with plaster-of-Paris. An opening in the plaster-of-Paris, and a proper arrangement of buckles, enable the surgeon to secure a progressive approximation of the fragments. In this manner, he had seen a gap of one and a half inches reduced to one-quarter of an inch in ten days.

Dr. Charles Phelps had frequently made use of the open method of operation and did not fear the results.

Dr. William T. Fluhrer's practice was to operate upon recent fractures of the patella, as it assisted an accurate diagnosis, and secured the quickest and fullest functional results, at the same time exposing the patient less to the danger of refracture. The infolded soft parts often interfered greatly with securing proper results, and he had been led to introduce a needle subcutaneously to push aside these tissues so as to free the fragments and obtain bony crepitus. There had been no accident in his operative cases, some of which were presented to the Section, and confirmed the statement concerning the good results to be obtained by this method.

In view of the strong opinions expressed by some against the operative method, and the excellent results exhibited by those who advocated operative procedures, Dr. Abbe said he thought that we should conclude that the operation and not the method had failed.

Dr. Bull, in closing the discussion, said that while appreciating the brilliant results obtained by operations, and in spite of their excellence and rapidity, he considered the methods too dangerous for general endorsement.

He had tried various devices which were attached to the skin for the purpose of securing better approximation of the fragments, but they had failed of their object,

NEW INVENTIONS.

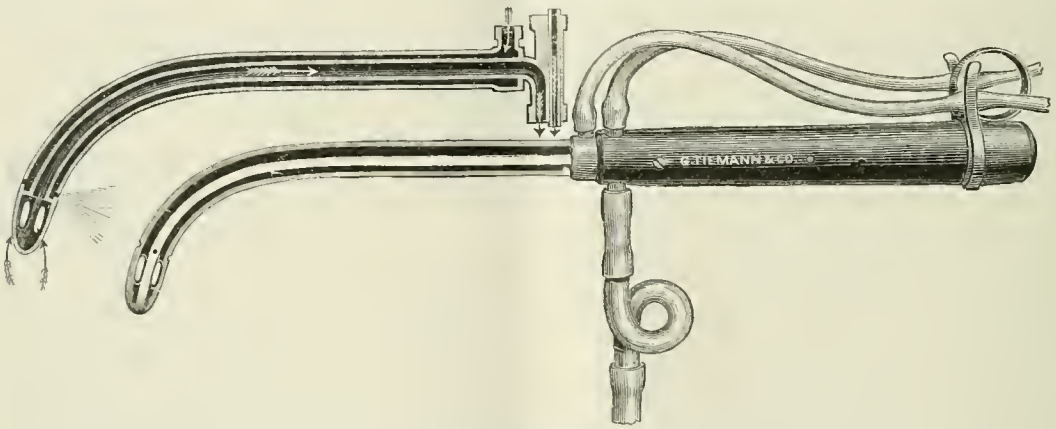
A SELF-EXHAUSTING IRRIGATING CATHETER.[1]

BY NATHAN G. BOZEMAN, PH.B., M.D.,
GYNECOLOGIST TO ST. FRANCIS'S HOSPITAL, JERSEY CITY; MEMBER OF THE NEW YORK COUNTY MEDICAL SOCIETY, ETC.

THE double-current catheter, or irrigating tube, which I have been using for some time, was originally devised by me for treating chronic cystitis in women after a fistulous opening had been made in the bladder, for free drainage and physiological rest of that organ. As the assistant of my father, Dr. Nathan Bozeman, I have carried out this treatment under his directions in a great many of his patients, hence the excellent opportunity for perfecting the instrument. By its use medicated fluids can be sprayed against the distended walls of the bladder in very fine jets, and be quickly removed, together with the urine, as fast as it accumulates in the most dependent portions of its cavity. The patient being in the supported knee-elbow position, or on the side, douching of the organ can thus be accomplished without wetting the clothing or causing vesical tenesmus.

The instrument consists of an outflow tube and supply tubes, which are made of silver or hard rubber, and a handle for convenience of manipulation. The four supply tubes, each having a calibre of one-sixteenth of an inch, are attached along the sides of the outflow tube. They are provided with small lateral openings near their closed extremities. The outflow tube has a calibre of three-sixteenths of an inch, it is conveniently curved, and at the junction with the handle it is bent downward at right angles. There are also lateral openings near its closed end. United to the short portion of the outflow tube, which is bent downward, and parallel to it, is a tube having a calibre of one-thirty-second of an inch, it projects upward sufficiently to form a connection for a soft-rubber tube. Suspended from the open end of the outflow tube and the lower end of the short vertical tube, is a series of small coils of glass tubing, united one above the other by soft rubber tubing, and from the lowest one hangs a long rubber tube. The handle is rounded, and is four inches long, and at its extremity it is provided with a ring and steel clamps for compressing two soft-rubber tubes.

When I use the instrument for washing out the bladder, the curved extremity is passed into its cavity through the fistulous opening in the vesico-vaginal septum, the patient being in the supported knee-elbow position, with the perineum elevated by a perineal retractor. In this position, and under these conditions, the bladder is usually distended, and the extremity of the catheter can be moved about in its interior, barely touching its walls. Now the irrigating fluid is allowed to flow into the instrument by freeing the two rubber tubes from the clamps which compress them. A very small portion of fluid passes directly into the coils of glass tubing, collecting in them and partially filling them, when it is precipitated *en masse* downward, carrying air with it, which is exhausted from the outflow tube. And the fluid which collects in the fundus of the bladder, after having been sprayed against its walls through the small openings near the extremity of each of the supply tubes of the catheter, is steadily drawn up and evacuated.



Self-exhausting irrigating catheter, drawn one-half size, also a median longitudinal section of the same, without the handle. The arrows indicate the directions of the currents.

I find for irrigating the bladder that two glass coils and a rubber tube suspended from them, twelve inches long, produce sufficient exhaustion. A continuous return current through the outflow tube of the instrument is thus kept up, and all the fluid, after lavage of the bladder, is emptied automatically in a vessel placed on the table between the knees of the patient

The deep grooves along the catheter were intended to serve as tubes when the mucous membrane comes in contact with them, in the expectation that through them air would be drawn into the instrument, thus preventing the sucking in of the mucous membrane, and the occlusion at times of the openings in the outflow tube. This often did occur, so I have been compelled to cut off one of the supply tubes and establish a permanent communication with the air, through it, with the inside of the outflow tube on a level with its lateral openings. Any possibility of suction on the mucous membrane is thus prevented.

[1] Presented at the meeting of the Alumni Association of the Woman's Hospital, February 27, 1889.

The employment of continuous suction in a very simple and efficient way in the application of this catheter, makes it different from any of the double-current catheters that I have seen. Besides the use for which I devised this instrument, I have employed it with great satisfaction for irrigating deep sinuses and pus cavities. During the operation for closure of urinary fistula, in the supported knee-chest position, it is invaluable for keeping the cavity of the bladder and the wound free from urine and blood.

9 West Thirty-first Street, New York City.

CORRESPONDENCE.

ST. LOUIS.

To the Editor of The Medical News,

Sir: Our Health Commissioner has just issued the usual annual summary of mortality statistics for the last year, from which it appears that the total number of deaths in St. Louis during 1889 was 8004, being 1011 less than in 1888, and 1151 less than in 1887. The annual death-rate per 1000 during the year in a population estimated at 450,000 was 17.78.

Of the total deaths, 2047 were infants under one year, and 3149 were children under five years; 4383 were males, and 3621 were females. There were 63 deaths from measles, 114 from scarlatina, 346 from diphtheria, and 93 from croup; 146 from typhoid fever, 223 from malarial fever, and 367 from diarrhœal diseses in children under five years of age. The total deaths from zymotic diseases were 1773. There were 655 deaths from consumption, 598 from pneumonia, 337 from bronchitis, 408 from convulsions, 255 from Bright's disease and nephritis.

The number of births reported during the year was 11,906, of which 11,390 were white, and 516 colored; 6088 males, and 5818 females.

The epidemic influenza did not pass by St. Louis altogether, but the visitation was very light as compared with that in several of the Eastern cities, and there were no special features that require mention.

In the St. Louis Medical Society a periodical source of contention has been the question, How and by whom shall the proceedings of the Society be published? For years the *St. Louis Medical and Surgical Journal* published them without competition. Later the *Weekly Medical Review* entered the field, and, as a weekly journal, secured the right to publish them, as offering more favorable facilities than a monthly journal well could. Later there was a disagreement between the publishers of both these journals and the Society, and the old *Courier of Medicine* published the transactions for a year. At the commencement of this year the war broke out again. Proposals from different medical journals were received by the committee and presented to the Society, and it was seen that the proposition of the revived *Courier of Medicine* was in some respects more liberal than that of the *Weekly Medical Review*, although the latter had the manifest advantage, for a society holding weekly meetings, of giving opportunity for more prompt publication of papers and discussions. When the vote was taken, the result was declared to favor the *Weekly Medical Review* by a vote of eight to seven, its editor having voted for his own journal, while the editor of the other journal had refrained from voting at all. At the next meeting evidence was given of active "wire-pulling" by the editor of the *Courier*, for the action of the preceding week was then reconsidered, and by a vote of twenty-nine to nine the publication was awarded to the *Courier*.

Two or three volumes have been published here recently which I may mention as of some interest to the profession. The first is entitled, *Directory of Physicians, Dentists, and Druggists of Missouri, 1889*. So far as the *Directory* itself is concerned I have no special criticism to offer, but in the advertising pages the publishers have directly and grossly insulted the reputable medical schools which patronized them, and the members of the profession who subscribed for the book, by introducing several disgraceful advertisements of quack remedies: such as "—— Cancer Hospital Great Infallible Indian Cancer Plaster; the only institution in the world where cancers and malignant tumors are permanently removed without using the knife, ligatures, or caustics," etc. Another "ad." is that of "Mrs. Dr. ——, the Female Specialist," who sets forth that she has "a lying-in hospital for female complaints." Another female practitioner advertises a variety of treatments, and, among other specialties, announces that "magnetism is the supreme feature of my baths; hence patients have choice of male or female assistants." Another practitioner announces that he can be consulted as an allopathic physician, but prefers under all circumstances to treat all diseases of either sex, and of any age, by the new medical system called "Dosimetry," etc.

But to turn to a more pleasant subject, I have just received a copy of Dr. W. A. Hardaway's *Manual of Skin Diseases*, a volume of some 400 pages, which not only does credit to Dr. Hardaway's ability to describe clearly and concisely the various diseases affecting the cutaneous surface, but gives the treatment which he has personally found to be most successful in these diseases. Dr. Hardaway's numerous friends will be glad to see this demonstration of his complete restoration to health after having suffered for a time from nervous prostration superinduced by overwork. I am happy to be able to state that there is no foundation for the story which was circulated some time ago, that he had lost his eyesight, further than that he dropped and broke a pair of eyeglasses which he had worn for some years.

Dr. D. C. Gamble, who has been connected with the Faculty of the Beaumont Medical College since its organization, as Professor of Otology, has tendered his resignation, to take effect at the end of the present term. It is probable that the chair which he has held will be combined with that of Ophthalmology, now ably filled by Dr. A. Alt.

VIENNA.

To the Editor of The Medical News,

Sir: At last we have heard the results of the bacteriological studies of influenza. Dr. Weichselbaum, Professor of Bacteriology at the Vienna University, and the discoverer of the coccus of pneumonia, has reported his work at a meeting of the faculty. He made a careful study of the sputum, nasal secretion, and blood of twenty-one cases, and in all of them the utmost precautions were used to get pure materials for examination.

Not only were microscopic examinations made, but in every case experiments upon animals were made with pure cultures; so that the utmost scientific care was exercised. He found in all the material examined large numbers of the diplococcus pneumonia, and in the pure cultures his results were verified, for the bacterium found could be distinguished in no way from the diplococcus. It had the same light-colored capsule and the characteristic appearance, and in pure cultures on agar and on gelatin the colonies were exactly the same. In his experiments in inoculating the smaller animals the results were the same as after inoculations of the diplococcus pneumonia. In a few cases streptococci were also found, but in small quantities. In his *résumé* Weichselbaum concludes that, in regard to the etiology of influenza, there are two possibilities; either the pneumonia coccus is the cause of the disease, or else it is caused by an unknown microörganism the action of which brings about conditions that make an excellent soil for the diplococcus, and diplococci very early entirely supplant the primary micrococci. The clinical history gives many points in favor of the first theory; the sudden chills and the rapid course and the great variety of air-passage complications. But we cannot explain the great differences between influenza and pneumonia if the same germ is the cause of both, unless we assume that the coccus has been so varied by unknown meteorological circumstances as to cause marked differences in its action on the human organism. The second theory—namely, that the diplococcus is merely a secondary infection, has many analogies, especially in the etiology of the exanthemata, and is the theory to which Weichselbaum himself inclines. The pneumococcus has often been found in healthy sputum, and grows exceedingly well on inflamed mucous membranes. It has great vitality, and probably the unknown influenza coccus has not. And thus the question stands. There have been many investigations throughout Europe on this point, but nowhere have more definite results been reached.

NEW YORK.

To the Editor of THE MEDICAL NEWS,

SIR: The proof of the old-time proverb, "It is an ill wind that blows nobody good," has been again exemplified in the history of the recent fire at the Presbyterian Hospital, and although that calamity was mercifully exempt from the usual horrors attendant upon a fire in a hospital, it has not been allowed to pass without impressing a useful and much-needed lesson upon the community. Among the first to heed the note of warning were the Commissioners of Charities and Correction, who ordered a general inspection of all the institutions under their care with especial reference to the provisions against fire. I say a much-needed lesson, for, outside of this department are to be found hospitals well appointed and well managed in most respects, which are still very deficient in their arrangement regarding fire. It is true that some of them have instituted regular fire-drills for the purpose of familiarizing those in charge, with the best line of action to be pursued in such an emergency; but the practical difficulties in the way of carrying out the exercises efficiently in a house filled with the sick and helpless are so great as almost to neutralize the good derived from such a system. The real danger, in some instances, lies in the faulty construction of the buildings, and not in the want of provision for extinguishing fires. Of what avail is it to have the most modern fire apparatus, ready for action at a moment's notice, and a corps of trained attendants capable of using it efficiently, if connecting corridors, elevator shafts, and sometimes a central chapel, acting like immense chimneys, assist the spread of the flames and convert the building into a veritable death-trap? A few hospitals have beds surrounded by curtains which are a constant menace, and I have often trembled at night when the orderlies were going from bed to bed, examining surgical patients by the light of a flickering candle, as I thought how easily a sudden gust of air might start a conflagration. I would not be understood as opposed to some contrivance for the privacy of the patients; but why use curtains, which not only increase the risk of fire, but furnish admirable lodging places for disease germs? It would not be difficult to secure privacy to the patient and avoid these undesirable features, by substituting for the curtains light wicker screens, such as are used about the beds in some of the London hospitals.

Dr. Frank Ferguson, who has just been appointed Professor of Pathology in the New York Post-Graduate Medical School, entertained the Clinical Society connected with that school, by a paper on the "Plasmodium Malariæ and its relations to the Malarial Fevers." This difficult subject, with which even a number of our active workers in pathology are but little acquainted, was made doubly interesting by the fact that the paper was based upon actual researches which had been carried on for some years by Professor Ferguson. He said that the clinical symptoms of malaria had been produced in animals by germs which had been isolated and cultivated, and that these germs had been afterward found in the bodies of the animals. Similar germs isolated from the marshes of malarial districts had been found to produce a like train of symptoms, and the pathological lesions characteristic of malaria had been observed after death; but strangely enough, the bodies which had been introduced were not found. It had occurred to him that it was possible that these germs had taken up the coloring matter of the blood and had become deeply stained by it; and he thought it possible in this way the changes which had been studied under the name of the plasmodium malariæ had been produced. His experiments made him feel positive that he could reproduce in animals at any time these changes in the protoplasm of the blood-cells.

Dr. J. M. Byron, of the Loomis Laboratory, in discussing the paper, said that while studying the blood in other diseased conditions, and noting the effects of various reagents, he had been struck by the similarity between the changes so produced and the so-called plasmodium malariæ of Laveran. Other pathologists had had a similar experience, and he was by no means convinced of the pathognomonic and bacteriological standing of this plasmodium. It has no definite form, and most of its forms and relations can be explained by contraction and change of the protoplasm of the red corpuscles of the blood—changes which are produced probably by an unknown bacterium.

The same gentleman told me that although attempts

have been made at the Loomis Laboratory by himself and others to hunt down the "influenza bacillus" of Seifert, and ascertain its relations to "la grippe," their work had been interrupted by the rapid subsidence of the epidemic, and they had been unable to arrive at any conclusions of practical importance.

INDIAN MEDICINE.

To the Editor of THE MEDICAL NEWS,

SIR: A paragraph in THE MEDICAL NEWS of January 18th reports Major Powell, of the U. S. Geological Survey, as saying that "To the Indian mind there is no medicine except sorcery."

If I understand this assertion correctly, it contains either more or less than the whole truth. I do not contend, however, that the use of "drugs" by savages is often, if at all, dictated by knowledge of their therapeutic effect, if they have any. But after their own fashion, they use many articles gathered from forest and plains.

If we take the Sioux or Dakota tribe for an example, we find that their name for doctor means "herb-root man." They sometimes apply to him also the name of "spirit man," as with them, if not with all savage tribes, the offices of doctor and priest are united in the same individual. Their pathology is spiritual, and the doctor must deal with spirits; but in doing so he finds roots and herbs scarcely less important as means than his rattle and his vocal chants. Many of the herbs used by him are well known to all who live in his region, but he generally manages to have some which he assumes to be known only to himself and the gods, and which are guarded with an air of secret wisdom.

A physician who labored among the Dakotas in Minnesota as far back as 1836, reported their medicine men as using a local species of euphorbium, with violent purgative effect, and as dressing external injuries with the inner bark of the pine. Also as using the American milk-weed, and quite a variety of roots and herbs and barks in no very intelligible manner—which we can readily believe.

I saw an Indian use dry earth as a dressing for gangrene. This, with the pine bark as a local dressing, points to something approaching rational surgery. It was also the common report amongst white "squaw men" and "half-breeds" that the old midwives possessed an herb or root which produced abortion, and which they sometimes brought into requisition for jealous wives who wished to "spite" their husbands for bringing into the wigwam a younger and fairer bride. Of this means of punishment I have no practical knowledge, though I have had to do with cases where the hunting-knife and the strychnine-bottle were resorted to as a more direct means of vengeance.

In 1869, being full of the missionary spirit, I was sent by the Commissioner of Indian Affairs as physician to one of the new agencies established in Central Dakota under the Sherman Commission, and continued in that capacity until the spring of 1876—long after the missionary spirit had left me.

These Indians were fresh from the plains and in constant intercourse and fellowship with those who still remained obdurate under Sitting Bull, Red Cloud, and lesser lights, and I had thus a chance to study the Indian in all his native wildness and ferocity. Possessing a soul superior to professional jealousy, I often shared the same patient with the native practitioner, who did not always receive my visits with that air of cordial generosity which should characterize so noble a calling. As often as otherwise I found my carefully compounded prescriptions hung upon the "medicine pole" outside the teepee, but I never showed any resentment on that account. I still loved good Indians, and it only required the shooting of three or four of my civilized companions within sight of the agency to convince me that none were good but those who occupied the scaffolds of the dead. I was correct in the main, but there was an occasional rare exception, of whom I love to think, now that they are dead also. The superstition which fills the savage mind concerning priests and doctors doubtless saved me from being shot down in my wanderings in search of the good that I might do.

Every family had its "medicine-bag" hung on a pole outside the teepee, but in spite of this the evil spirits would slip in now and then. If the patient was very ill, the teepee was abandoned to the sufferers and the doctors, the family taking refuge elsewhere. The use of the rattle was only limited by the endurance of the medicine man. His hideous vocal accompaniment was limited by the endurance of the larynx. When exhausted with these efforts the doctor would grab his gun with the air of a man who was struck with a new idea, and run out and fire at the spirits. Then while gaining further strength, he would burn aromatic herbs upon the coals in the fireplace, until the teepee was odorous with more pleasant things than usually greeted the civilized nose in an Indian habitation. He would also make decoctions and warm infusions, some of which he would cause the patient to sip, but the major part went into his own mouth, and was thence spurted over the body of the patient.

If there was severe local pain, the doctor would suck the part, first concealing some strange object in his mouth, which in the end he would exhibit as the offending evil which he had sucked out, when, if the patient was endowed with proper faith, the pain would cease. Another feature of the trick was to spit blood which was supposed to have come out with the offending object, but which he drew from his own gums by irritating them with the foreign body.

As a case in point, I was attending a young woman suffering with acute articular rheumatism. I arrived at the teepee one day to find the medicine man sucking at her knee. In due time he raised his head suddenly and drew his hand with a quick motion over the knee, when something struck the opposite side of the teepee and fell to the ground. With an air of profound gravity he walked over, picked it up, and exhibited to the patient an eagle's claw, wet with saliva, and assured her that that had been causing her pain, and that he had sucked it out. I looked duly surprised, gave the patient a full dose of opium, and agreed that she would feel easier.

So we see that the Indian uses "medicine" for irrigation, for fumigation, and for imbibition; and that he is also a masseur and faith-healer.

In surgery, as we have already seen, he uses barks, roots, leaves, herbs, and dry earth for dressings. He also constructs good splints from small, flexible willows,

which accommodate themselves to the shape of the limb, and by numbers supply the needed strength. But in the treatment of fractured clavicle he is a failure, judged by the results I have seen.

They employed one means of treatment which I sometimes utilized. That was the hot-vapor bath. Their mode of using it was to construct a small "wicking-up" of willows, large enough to sit under, which they covered with robes or blankets. Large stones, well heated, were placed in the centre. Stripped and crouching about these stones, the patient poured water upon them, and in the heated vapor thus produced would sweat very freely. This device was in use by the Dakotas early in the century, and how much earlier is not known.

One old doctor assumed an air of fraternity toward me, and would come into my office with a look and a greeting which said plainly, "we know how to fix 'em." He observed quite early in our professional acquaintance that when the bowels were torpid, the medicine which I gave made them act; and that if there was too much action, my medicine stopped it. The fact took great hold upon him, and he came to me regularly for supplies of this medicine. I gave the pills in bottles which he readily distinguished, and the doses also were readily remembered. He also drew regularly supplies of camphor, but all that I could learn from him of its use was that he "made medicine" with it. He probably fumigated the teepees of the sick with it, and was thereby enabled to produce an odor which no other "medicine man" could produce.

He also wanted chloroform, but for obvious reasons I refused the request and assured him that it was "good medicine" for white men only. The virtue of the Sioux women in the wild state was superior to "the world, the flesh, and the devil." Applications were not very infrequent from enamored "warriors" for the medicine which, held to the nose, "made people sleep so that an arm could be cut off without awakening the sleeper." Many did not hesitate to say that they wanted to put it to the nose of the object of their adoration, so that they might accomplish what was otherwise a hopeless undertaking.

NEWS ITEMS.

Cholera in Persia Apparently Abating.—From recent reports, through Russian channels, it seems probable that the cholera epidemic of central Asia is abating. In Persia the march of the disease has been checked by quarantines between the cities and the mortality in several of the infected towns is lower. In regard to Mesopotamia, also, favorable reports have been issued by the Turkish Sanitary Board; a report dated in January, goes so far as to say, "Mesopotamia is now free from cholera."

A Philadelphia Physician in Africa.—Dr. W. L. Abbot, of Philadelphia, has recently arrived at Zanzibar, from the interior of East Africa, where he has been engaged in making explorations and scientific collections, some of which are for the Smithsonian cabinets. Some of his expeditions into the Kilimanjaro table-lands were made in company with Mr. Thomas Stevens, the commissioner of the *World* to discover Stanley; and as a consequence, Dr. Abbot's experiences have been pretty fully described. One of the troubles that he and other explorers met with in Africa is leg-ulcer, which is largely in excess of any other disease. Dr. Abbot, writes a correspondent, "had his clinic, before breakfast, nearly every morning, and it seemed as if nine-tenths of his cases were leg-ulcers." Dr. Abbot was graduated from the University of Pennsylvania, in 1884.

The Diagnosis of Hydrophobia.—Dr. Gibier, of the Pasteurian Institute, in New York City, has received many letters of inquiry as to the diagnosis of rabies in dogs which have bitten human beings, and thereupon killed. In such cases, he requests that some part of the brain of the animal be put in glycerin, with as little delay as possible, and be sent to him. When this is done, but not otherwise, a satisfactory conclusion can be reached.

The Sale of Antipyrine Officially Restricted in Vienna.—The *British and Colonial Druggist* states that no less than seventeen deaths from overdoses of antipyrine occurred during a fortnight in Vienna. This was during the prevalence of *la grippe*, when the sale of the drug was enormous; and until recently it could be bought freely by the laity. Since then, and partly in consequence of those fatalities, the sale of antipyrine has been forbidden except upon the prescription of a physician.

The Oldest Living Graduate of the University of Pennsylvania.—Concerning the question of the oldest living graduate of the University of Pennsylvania, a correspondent calls attention to the fact that Dr. James Kitchen, of Philadelphia, was graduated from that institution in 1822, at the age of twenty-two years. He is now ninety years of age, and has been engaged in the practice of medicine for sixty-eight years.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 11 TO MARCH 17, 1890.

DAVIS, W. B., *Captain and Assistant Surgeon.*—The leave of absence for seven days, granted by Orders No. 9, Fort Preble, Maine, March 7, 1890, is hereby extended ten days.—Par. 6, *S. O. 58, Division of the Atlantic*, March 12, 1890.

By direction of the Secretary of War, RUDOLPH G. EBERT, *Captain and Assistant Surgeon*, now on sick leave of absence, is relieved from his present station, Fort Pembina, North Dakota, and will report in person to the commanding officer Angel Island, California, for duty at that station.—Par. 1, *S. O. 57, A. G. O.*, March 10, 1890.

By direction of the Secretary of War, JUNIUS L. POWELL, *Captain and Assistant Surgeon*, is relieved from duty at Fort Supply, Indian Territory, to take effect at the expiration of his present leave of absence, and will report in person to the commanding officer Fort Randall, South Dakota, for duty at that post, and by letter to the commanding general Department of Dakota.—Par. 8, *S. O. 56, A. G. O.*, March 8, 1890.

ORIGINAL LECTURES.

HEPATIC FEVER.

The Middleton-Goldsmith Lecture for 1890, delivered before the New York Pathological Society, Jan. 15, 1890.

BY WILLIAM PEPPER, M.D., LL.D.,
OF PHILADELPHIA.

MR. PRESIDENT AND MEMBERS OF THE NEW YORK PATHOLOGICAL SOCIETY: Your President's kind introduction adds to the embarrassment which I confess to have felt in endeavoring to select some subject which might more or less worthily occupy the attention of such a body; in casting about for such a subject, I found much difficulty, and that which I finally chose will possibly be regarded as scarcely appropriate. It is not wholly pathological, but partly clinical in its interest. The very name "hepatic fever" may seem more or less a misnomer. We meet with so many affections of the liver attended with fever, that it would be impossible to place in one group all to which this name might in one sense be applied.

It is true that, without calling in the assistance of our willing brethren, the laparotomists, we are, at times, unable to make an exact differential diagnosis, and are still forced to name the affection by the most prominent symptom. And I am sure you have all met with cases of lesion of the liver or of its ducts, attended with fever of the peculiar type I wish to describe, and in which the determination of the exact seat and kind of the lesion was difficult or impossible. I do not intend to speak of the more ordinary fever which attends many acute hepatic affections, which is merely a more or less severe continued febrile movement with moderate fluctuations. We note this, for instance, in acute catarrhal jaundice, or for a few days following the passage of a gall-stone. Nor do I now include that very interesting affection, known as Weil's disease, of which, I believe, I have seen three cases, although only in one have I a full clinical and pathological record. What I shall say is based on a study of twenty-one cases, where fever of a peculiar paroxysmal character appeared in connection with various hepatic lesions. It may either be a quotidian, a tertian, or a quartan; and I have even seen a double quotidian type. It is a distinctly paroxysmal fever, often ushered in by a violent chill, shaking the whole body of the patient. Sometimes there is only a slight rigor, sometimes it even comes on without any perceptible sensation of cold at all. This is followed by an unusually rapid rise of temperature, reaching as high a point even as 103°, 104°, or 105°, attended with distress, restlessness, thirst, more or less pain through the frame, and not rarely with vomiting; lasting for a few hours—from four or five to as many as ten or twelve—and terminating by a sweat, sometimes merely a moisture, sometimes a drenching sweat soaking the clothing of the patient and bed. This fever may be repeated, as I have said, at quotidian, tertian, or quartan intervals; a single paroxysm may close it, or there may be successive paroxysms, the intervals being sometimes regular and sometimes wholly irregular, amounting to days, weeks, or even months before another attack appears. After each paroxysm, jaundice makes its appearance as a rule; but sometimes it is only slight, or may even be absent, with at most a little yellowish discoloration of the conjunctiva and some darkening of the urine for a short time. In the majority of cases, however, the jaundice is decided, and may be intense, lasting for varying periods, sometimes days, sometimes several weeks, before passing away. At the moment of the occurrence of such a paroxysmal fever, there may or may not be severe hepatic pain. This pain may be wholly absent, and yet a hard chill, high fever, profuse sweat, and deep jaundice follow. Or there may be pain so severe that it forces the belief that a calculus is engaged in one of the ducts—the pain requiring hypodermic injections of morphine for its relief.

In bad cases, where such paroxysms recur, you can easily understand that the general health of the patient suffers severely. Anæmia is developed; there is marked loss of flesh; the digestive processes are impaired; and we find these paroxysms recurring with greater and greater facility; in fact, in this type of hepatic fever, an unfavorable prognosis often has to be made, and many such cases go on to a fatal result after a course of variable duration. But it is far from being always fatal, and in a certain number of cases—it has been my own good fortune to see quite a number of them—after having from fifty to one hundred paroxysms, complete recovery occurs, without anything to signalize the termination of the process—no morbid discharge, nor passage of a calculus, but a gradual subsidence of the morbid condition itself.

It is to this type of fever, paroxysmal and intermittent as a rule, with paroxysms occurring sometimes closely together, with a certain amount of febrile action kept up between them, that I would ask your attention this evening.

It is not in connection with the liver alone that we meet with fever of this type; I shall later ask attention to the resemblance existing between this and urethral fever, where we find in connection with certain morbid states of the urinary tract, febrile paroxysms having considerable analogy with those already described.

In trying to understand a febrile process of this kind, it is clear that we must have in view the general causation of fever, and I take it, that we are all agreed to-day that fever comes very often as a septic process from absorption into the system of some morbid, pyrogenic, poisonous substance. And, secondly, that fever is caused by a disorder of the nervous apparatus controlling heat production and dissipation, and that this disorder may either be centric directly, or may be induced by

reflex irritation from some local disease. The reality of this last cause of fever, I think, may be demonstrated by the interesting physiological experiments which my distinguished friend, Dr. H. A. Hare, is bringing to a conclusion in the laboratory of the University of Pennsylvania, which show that a lesion which engenders fever will not do so provided all the nerve-trunks of the limb be severed; in other words, that in certain cases we must recognize, as a cause, the existence of a local lesion acting upon the heat-controlling mechanism at the centre in a reflex manner.

When we come to apply these general thoughts upon fever to the subject of fever connected with the liver, we would expect, I think, from the known antiseptic properties of the bile, to find certain difficulties in the development of fever; whereas, on the contrary, it seems to me, clinically, that there is no organ in connection with which we find more violent explosions of fever than we do in the case of the liver. It is very certain, however, that the entrance of bile into the blood cannot be brought into account to explain the production of fever. The injection of the entire bile, or the injection of bile-salts, both lower temperature, slow the pulse, and slow breathing, but do not create fever at all. Again, bile may lie for a long time, even for weeks, in an obstructed duct, and undergo no morbid change which makes it pyrogenic. It is perfectly true that the bile, a highly complex liquid, is singularly prone to undergo chemical change—bilirubin becomes converted into biliverdin in the easiest manner possible. But this is a chemical change, and is not one attended with the development of septic principles; so that the bile may remain a long time in the obstructed dilated ducts without undergoing changes rendering it capable of producing septic processes or pyrexia.

It seems, then, necessary, in these cases, that we should recognize the existence of additional elements; that there should be mixture with the bile of morbid discharges from the mucous membrane of the ducts; and it is very clear that this could be brought about in almost any case very readily. Thus, for instance, the passage of a gall-stone frequently leaves a laceration of the mucous membrane. We have, then, at once an abrasion, a source of morbid discharge and admixture with the bile of putrefactive matter, and this may be sufficiently considerable in amount to alter the character of the bile and start a septic process.

Or, again, this same lesion serves as the starting-point of reflex irritation, to disorder the heat-controlling mechanism. Note, in connection with this, that most of the cases we are discussing are attended with more or less obstruction of the ducts of the liver, and think how often it is, in studying our cases of liver disease, that we recognize the existence of such obstruction. Now, when the ducts of the liver are obstructed and distended with accumulated bile, not only is the bile absorbed into the lymphatics if the pressure goes beyond a certain point, causing absorption-jaundice, but this pressure upon the hepatic tissue about the distended ducts interferes powerfully with the functional activity of the liver.

The bile-secreting function of the liver is certainly far from being its only important function. I doubt not we have yet to learn of new functions of essential value; but there is one we already know enough about to assert that it is of immense importance, and, so far as the production of disease is concerned, of even greater importance than the bile-secreting function, *i. e.*, the ptomaine-destroying function of the liver.

The liver, then, possesses this extraordinary power of arresting pyrogenic substances such as the albumoses, whether hemi- or deutero-albumose, as they are passing into the system from the intestinal canal, and of destroying their morbid properties. So that, granting the functional activity of the liver, these pyrogenic substances are not able to penetrate the system and generate pyrexia.

If you have a condition of the liver where the bile-ducts are distended with accumulated bile, not only, I say, does jaundice occur, but inevitably we shall have this important ptomaine-destroying function of the liver more or less paralyzed; and there will pass on into the system, on account of this arrest of the functional activity of the liver, pyrogenic and poisonous substances which may be responsible for the fever and other symptoms which subsequently develop.

The mere absence of bile from the intestine in cases of occlusion, even though it be a complete absence, is not immediately disastrous provided the diet of the patient is carefully regulated, and especially if fats be excluded; for, in the absence of bile, the fats break up rapidly into highly injurious derivatives in the intestines.

Thus I may quote the case (No. 1) of William McF., a man aged sixty-five years, who was admitted to the medical ward of the Philadelphia Hospital on September 2, 1870. The history obtained showed that he had enjoyed good health until four months before admission, when jaundice gradually appeared. The yellowness grew steadily more and more marked, and he lost flesh and strength rapidly. He had never suffered from an attack of hepatic colic, and the present sickness had come on without pain. On admission the jaundice was intense, affecting the conjunctiva and the whole cutaneous surface. His mind was clear but dull, and he usually lay in an apathetic, lethargic state. His weakness was so great that he rarely left his bed, and his emaciation was extreme. There was entire anorexia; the bowels were constipated, and the stools grayish-white in color, tough, and very offensive. No free fat was observed in the stools. The urine was rather scanty, and contained no albumin, but was dark brown in color. Tests showed the presence of abundant bile-pigment, but on applying to it Hoppe's test for bile-acids, none were detected. The abdomen was meteoric. The area of hepatic dulness was normal, and no tumor or irregularity of the surface of the liver could be felt. The gall-bladder could not be detected. There was no tenderness over the liver. The skin was usually dry; perspiration, when it occurred, was deep yellow. There was at no time any fever.

At the autopsy all the viscera were deeply stained yellow. The kidneys contained numerous large cysts. The liver, of normal shape, was somewhat enlarged in size, but much more dense and heavy than normal, weighing five pounds. The liver tissue was deeply stained with bile, and coarse-grained, as though in the first stage of cirrhosis. The radicles of the gall-ducts throughout the organ were much dilated and filled with grumous bile. The larger branches of the hepatic ducts, as the transverse fissure was approached, contained numerous polygonal brownish-black gall-stones. The hepatic duct

itself was enormously dilated (at least one inch in diameter), and was filled with very numerous calculi. These calculi, for the most part, measured one-fourth to one-third of an inch in diameter. There was one, however, fully two-thirds to three-fourths of an inch in its measurements, and with rounded edges, which was firmly impacted in the hepatic duct, just above its juncture with the cystic duct. The common duct itself was somewhat dilated, either from the previous passage of smaller calculi, or, more probably, from the dilating action of the impacted stone. The gall-bladder was considerably distended with light-colored bile, and contained numerous minute blackish calculi. There was no thickening, inflammation, or ulceration at any point of the biliary passages.

Here had been prolonged and entire occlusion of the hepatic duct, and yet no hepatic fever had resulted, because at no point in the biliary passages was there evidence of abrasion or inflammatory action; there had simply been resorption into the body of the normal bile. The patient's health had suffered from this protracted occlusion very much more markedly than was observed; for instance, in the well-known case reported by Bristowe, of London, where, for a long time, a patient was under observation with a biliary fistula. A tube had been introduced into the duct so that all the bile escaped externally, none entering the intestine, as shown by the condition of the fæces and of the local lesion, and yet there was very fair maintenance of the patient's health. There are a few similar cases on record. I will add the record of another interesting case of obstruction of the bile-ducts without fever, which was under my care lately.

Case II.—H. N. B., aged seventy-five, began to feel sick December 20, 1887, at which time he weighed one hundred and sixty-five pounds. Twelve years previously, about 1876, he had a spell of pain followed by jaundice. He also had several spells about 1883. Subsequently he was pretty well up to September, 1887, after which he had occasional slight attacks of pain in the region of the liver, followed by a little jaundice, and then had a severe attack on December 20, 1887, and a second one in February, 1888. After this they occurred almost every week and the jaundice was constant, though fluctuating in degree and passing away somewhat in the intervals. He had no fever at any period in the course of his case, but had, however, occasional sweats, chiefly of the legs.

He came under my care in April, 1888, when he was losing flesh rapidly and was constantly deeply jaundiced. The urine contained bile, but the fæces were not putty colored. Examination showed slight enlargement of the liver, but no mass could be found nor was the gall-bladder distended. There was no tenderness on pressure over the liver, but only a deep-seated sense of discomfort. He continued to have occasional spells of pain, with deepening jaundice but without fever, until summer, when he went to his country seat and I saw him but occasionally. He now had a series of very alarming spells with slight chills, followed by pain, prostration, and sweating, but without fever; there was constant deep jaundice. On July 8th, he had an alarming spell, during which he fainted and immediately afterward discharged a large amount of golden-yellow thick bile by the bowel, estimated at two pints. He continued to discharge this in smaller amounts for three days and then seemed to improve. On July 28th he had his worst spell, fainting and lying unconscious for an hour and a half. After this attack the pain, which had always been over the liver, about the short ribs on the right side, suddenly changed and was in the middle, below the umbilicus; and he never had any pain in the hepatic region afterward. From this date until October 31st, every stool was examined but no calculus was found. The stools were very varied, sometimes in ribbon shape, sometimes round; but whether flat or round, they were always grooved as if forced past some round hard object. Their color was at times brown, green, and white, and at other times there was a light green liquid, but no pus was seen. From July to December he had numerous spells of pain always low down in the middle of the belly; and in such attacks he always had impaction of the cæcum, requiring laxatives, which would bring away ribbon-shaped fæces. After August his only treatment was rest, massage, careful diet, and olive oil. He was so reduced that he weighed only one hundred and ten pounds, and so very anæmic that he fainted on several occasions. His last spell of pain was on November 25th, after which he gradually and steadily improved. He is now in perfect health, in his seventy-eighth year, and weighs as much and can walk as briskly as at any time for years past.

I believe that this case was one of large calculus with accumulation of bile behind it; and that the calculus escaped into the intestine and remains fixed there, probably in a pouch of the colon, up to the present time.

I have spoken thus of the mere occlusion of the bile-ducts, and of the fact that they often give rise only to these distention-results without hepatic fever. It is probably true, as already stated, that extreme distention may favor the admission of pyrogenic substances by impairing the ptomaine-destroying function. But it must also be noted that after occlusion has lasted some time, the irritation of the wall extends to the connective tissue surrounding the duct, and we have set on foot a peri-angiocholitis, which may spread, more or less extensively, through the organ. Not only this, but when morbid discharges occur and mix with the retained bile, we may find either a large abscess or a number of small miliary abscesses scattered through the liver even to the capsule. Thus it is that in some cases of occlusion we have no fever, and in others the typical form described is present.

If we now try to explain the apparent periodicity which occurs in some cases of hepatic fever, it seems attended with considerable difficulty. If there be a fixed lesion, as, for instance, a suppurative inflammation of the gall-bladder, there we have a distinct pus-forming centre, and we may have a true pyæmia. Naturally, in such cases, we find an explanation for the febrile process with regularly recurring, often quotidian paroxysms, just as we find with a pus centre of similar character elsewhere in the body. But in those cases, and they constitute the majority of the cases, where the paroxysms do not recur every day or every third day, or with any regularity, and yet recur frequently, it seems as if we must assume the existence of a lesion not continually sufficient to cause fever, but which is extremely liable to be increased by external causes.

Take, for instance, a catarrhal angiocholitis, an inflam-

mation of the bile-ducts of a catarrhal character, with a certain amount of thickening of the walls of the ducts, and a relaxed and enfeebled condition of the system; here is a state singularly prone to exacerbation and increase from external causes—such as a chilling of the surface or an indiscretion in diet; increased swelling of the mucous membrane and total occlusion of the ducts are the results, and there is a mixture with the bile of the morbid discharges from the inflamed mucous membrane, and at the same time an intense local irritation acting upon a system which has become highly sensitive.

I shall read to you the notes of a case where a long-continued series of these paroxysms were evidently explicable on this supposition.

Case III.—H. B. D. came under my care on March 19, 1888. For many years he had been greatly exposed on the plains in the West, subsisting on coarse food. His best weight was one hundred and fifty, but for twenty years it was not above one hundred and thirty-five. In 1880 he had congestion of the lungs in Texas, and has been susceptible to colds since then, catching cold frequently every winter. He had diarrhœa through the summer of 1885; and again in the summer of 1887. He was in the West, exposed to intense heat, and had returned to Nantucket, where in August he had his first chill, and has had chills since then at irregular intervals, from daily up to seventeen days apart. The chills were severe at times, lasting distinctly for an hour. They were followed by fever (102½° to 104°), ascending for from six to twelve hours and then quickly dropping, so that the temperature within two or three days was almost normal. No treatment prevented their return. At about the same time (September, 1887), pain began to be felt in the right side; but on one occasion only were the chill and attendant pain so violent that hypodermic injections of morphine were required. Jaundice first appeared in October, 1887, and has continued more or less since, at times very deep, at other times almost absent. It always comes promptly after a chill, when the urine also becomes very high-colored. The stools are light but never clay-colored, and always have contained bile.

When I first saw him I made the following note: the chills now recur about twice a week, but irregularly. The patient has progressively lost flesh and strength. Ascites appeared February 15, 1888, and has increased, so that now it is very considerable. The urine contains a small amount of albumin, specific gravity 1021 to 1023; with abundant indican at all times. It was extremely difficult to obtain the reaction of biliary coloring matter, and repeated tests gave negative results. But on getting the urine perfectly fresh and preventing decomposition of the bilirubin by the addition of a little ether it was obtained. This observation seems important as bearing on the rapidity with which the organic bodies in the bile may break up, whether or not from bacterial action, and thus bearing also upon the development of irritating ptomaines in obstructed bile-ducts.

The diagnosis adopted was that of severe catarrhal angiocholitis, and the result verified it. Paracentesis of the abdomen was performed three times and several gallons of clear yellow serum were withdrawn each time. The patient was treated with absolute rest in bed, rigidly strict diet, and alternating courses of nitrate of silver and potassium iodide. He took at first twenty-five grains of silver, then after an interval of a month fifteen grains, after another interval fifteen grains more, and subsequently took it at short periods when spells recurred. Careful study showed that there had been no periodicity in the chills and that they had always been produced by exertion and exposure. He had finally become so sensitive that the most trivial exposure was sure to be followed by a severe chill. The ensuing fever, running up to 103° or 104°, was followed by profuse sweat, intense jaundice, and furious itching. His restless spirit led him to rise as soon as he was able, and immediately after doing so there would come another spell. In this way a certain semblance of regular recurrence was produced. After he was confined to bed the spells subsided and soon ceased; and he had none as long as I kept him in bed, which was nearly four months; at the end of which period he was almost free from jaundice, had no ascites, and had gained flesh and strength. He immediately began to overtax his strength and to expose himself. He would then take cold and have a recurrence of jaundice; but as the tone of his system improved, and with the improvement in the local conditions, there was continually less and less fever with the spells, though it was not unusual for it to go up to 101½° and 102°. The urine continued to contain a trace of albumin, and occasionally a hyaline cast would be found. The blood showed, at different times, from sixty increasing to eighty-five per cent. of hæmoglobin and from 3,400,000 up to almost normal of red-blood globules. His improvement was thus progressive but fluctuating and the case required constant, close watching. For instance, after being entirely free from fever and jaundice, all summer at Nantucket, he overtaxed and exposed himself in September, 1889, in New York, and brought on a chill with high fever and return of jaundice, which confined him to bed for more than two weeks. Since then he has improved steadily and is now in very good health. He is travelling in the West and is using a drachm of glycerin twice daily with potassium iodide.

In the following interesting case the symptoms and the course of the disease were very similar to those just narrated.

Case IV.—Henry E. K., aged forty-nine, seen in consultation with Dr. E. E. Montgomery. He had catarrhal fever with jaundice, in August, 1889, and since then has not been well. He is a finely built, large man, who had not had a day's illness in thirty years. He is abstemious in habits, but has worked very hard and had much responsibility. During the past two or three years he has had several mild attacks of hepatic colic, but no jaundice. He was slightly jaundiced in September, and then had chills and fever of tertian type for several weeks, which were not controlled by quinine. The chills varied in intensity, being sometimes slight, but occasionally severe, with shaking. They occurred at different periods of the day, but usually in the morning, and were followed by fever, of from 102° to 104°, lasting into the night, and ending with a sweat during the night, so that the temperature was down on the following morning. The jaundice that followed was variable both in depth and duration. During twenty-four hours, when he

had one of these spells, he passed about thirty-five ounces of urine containing 1.9 per cent. of urea, or about 300 grains in all. The appetite was poor, the stools clay colored and either loose or costive, but he had no severe pain or soreness in the region of the liver. On November 1st he had a sharp chill, and three days later a mild chill, and then violent pain and deep persistent jaundice. He continued to have chills and fever with increasing frequency throughout November and December; they would recur upon any exertion or exposure. Even after he was kept continuously in bed and upon an exclusive milk diet, he had several, but with decreasing severity and at increasingly long intervals. There were fulness and a slight sense of resistance in the region of the gall-bladder, with slight relative impairment of resonance over the duodenal region. No calculus was ever found in the fæces. He was confined rigidly to bed for a number of weeks. Repeated blisters were applied over the region of the gall-bladder. He took alternating courses of silver nitrate with opium and belladonna and of potassium iodide. The jaundice has now completely passed away. There has been no spell for a considerable period; he is rapidly regaining flesh and strength.

Without dwelling upon a question of diagnostic interest, I would call special attention to the importance of estimating the daily amount of urea excreted during such paroxysms, in order to establish or refute Regnard's statement that, in distinction with what occurs in malarial paroxysms, the amount of urea excreted is reduced in hepatic fever.

In considering the mechanism of attacks in such cases as these, we are struck by the presence of intense local irritation and of probable septic action. There is occlusion of larger or smaller branches of the bile-ducts— not necessarily of the main duct, since bile may be constantly present in the fæces — so that the network of ducts in only a small area of the liver may be involved and the mucous membrane be in a state of chronic catarrhal thickening. After each of the first few paroxysms the patient promptly returns to his usual habits and, sooner or later, induces a renewal of inflammation with obstruction and all the symptoms of an attack. The system soon passes into a morbidly sensitive and pyrogenic state; the heat-controlling mechanism becomes so easily disturbed that mere reflex irritation from a spot of exaggerated catarrhal inflammation may suffice to bring on a spell: but, in addition to this, the lesion of the mucous lining of the affected bile-ducts becomes more and more serious, and complete obstruction more and more readily produced. The morbid discharges from the inflamed mucous surface, which have been escaping with the bile, are then retained and induce septic changes in the contents of the ducts. There is thus the double element of acute local irritation acting on a system in a state of exaggerated sensibility, and a source of septic infection acting on a system where the ptomaine-destroying function of the liver is more or less impaired from the distention of the ducts.

It will be seen at once that in such cases the diagnosis from hepatic abscess must be considered with the greatest care. Certainly in Case III. (H. B. D.) it seemed at first as though there must be grave organic disease. A careful consultation was held in regard to laparotomy after the first paracentesis; but after repeated examination I was unable to satisfy myself that the condition justified even exploratory puncture. After prolonged confinement to bed, it became evident that the hepatic fever was not connected with a fixed suppurating centre from which septic absorption was taking place, but was connected with a varying degree of angiocholitis, and that the gravity of the symptoms was even more dependent upon the constitutional condition of the patient than upon the seriousness of the local lesion. The complete recovery of the patient has confirmed this view, and the rapid progress of H. E. K. toward recovery justifies a similar diagnosis in his case.

While it is true that, in occlusion of the ducts, there may be only dilatation of the smaller ducts above that point, with alteration and atrophy of the cylindrical epithelium and, of course, with some interference with the functional activity of the liver; it must not be forgotten that there is constant danger of such dilated ducts becoming attacked with inflammation which will rapidly result in more serious lesions. The retained bile becomes grumous and decomposed, containing shreds of detached epithelium and flakes of muco-pus; suppuration occurs in the connective tissue adjacent to the ducts, and a section of the liver may show disseminated miliary abscesses, sometimes closely clustered around the main duct and sometimes situated at the ends of minute ducts, so as to show as yellowish points immediately under the peritoneum. In other cases the process may go on to the production of a large single hepatic abscess. In cases where such suppuration is escaped, but where the angiocholitis is severe and deeply seated, the inflammation of the connective tissue around the ducts may go on to the gradual production of one type of cirrhosis of the liver; and you are all doubtless familiar with this development as a result of recurring catarrhal inflammation of the bile-ducts.

While, however, the cases above reported show that even when there have been very grave lesions, doubtless short of actual suppuration, the insistance upon protracted rest and rigid hygiene with suitable treatment may cause a gradual subsidence of the angiocholitis with return of the functional activity of the liver, I suspect that in the great majority of cases of hepatic fever, such as I am describing, there is pus present at some point about the liver. The suppuration may, as in the following case, be seated in the gall-bladder and also take the form of a miliary abscess close to the peritoneum; of course, defying operative interference.

Case V.—Mr. F., aged sixty-three, consulted me on September 16, 1889. He had typhoid fever in 1882, and since then had often had pain in the back of the head. In the spring of 1887 he had several spells of hepatic colic—in all probability with gall-stone—followed by deep jaundice and intense itching. In the intervals between these spells he apparently regained his usual health, but for the past year had clearly been failing. He had lost much flesh, had suffered from insomnia, and recently albumin had been detected in the urine. He had also had several severe spells of hepatic pain, each time followed by fever and by local tenderness and deep jaundice. Thus, in March, 1889, he had a severe spell of pain in the region of the liver, lasting nearly all day, followed by jaundice for six weeks with severe itching; and another in April; but all was cleared up in June or

July. He had another spell in August, and had been deeply jaundiced since then, and his general condition had failed more rapidly. I found his urine, with a specific gravity of 1010 to 1013, neutral or slightly acid, with a moderately thick ring of albumin, and with quite numerous epithelial and granular casts; no sugar. This condition of urine persisted until his death, on November 12th. There was marked tenderness over the bile-ducts. In spite of continued rest in bed, and with very careful diet, repeated small blisters, and, internally, silver nitrate with belladonna, and olive oil, he continued to have, at short intervals, recurring spells of pain, followed by deeper jaundice, worse itching, and more tenderness. In each of these spells there was distinct fever, but he had no severe chill until about November 1st. From then until death he had, almost daily, a violent chill with chattering of teeth, followed by rise of temperature to 105° and ending in a profuse sweat. The jaundice now subsided decidedly, although he still remained somewhat yellow. The stools had never been putty colored, but only yellowish, and now were brownish. The urine cleared up, but continued to show the features as before stated.

Post-mortem held thirty hours after death. Body somewhat emaciated; jaundice marked; rigor mortis present.

Abdomen alone examined. On section, there was found a good layer of fat in the subcutaneous tissue of the abdominal walls. All of the tissues bile-stained. Omentum very lightly adherent by fine bands to the parietes at scattered points. The liver protruded below the costal margin about three-fourths to an inch; was adherent over the posterior, upper, and right lateral surfaces to surrounding parietes of abdomen, by universal adhesion rather than by bands. This adhesion was most marked posteriorly, where considerable difficulty was experienced in liberating the organ. There was no collection of pus in the peritoneal or retro-peritoneal spaces. *Spleen:* Large, soft, and of a pinkish-buff color. Pulp diffluent and grayish, but without purulent character; typical high temperature spleen. *Kidneys:* Large and coarsely lobulated. Capsule stripped off with moderate ease. On surface of right kidney was a cyst of about the size of a marrowfat pea, containing dark fluid. Surface of organs finely granular. On section: vessels distinct and striation very plain; slight decrease of cortical area. Pelvis and ureters normal.

Stomach, *duodenum*, *pancreas*, and *liver* were removed together. The *pancreas* was partly bisected and a probe placed in the duct, which was found to enter the duodenum at the papilla in the normal position. The gland tissue was, to the naked eye, normal. The *duodenum* and *stomach* were opened along their anterior face, and were found to be normal. The pyloric ring was of proper calibre.

The *liver* was large, rigid, and firm, of a slate color, and with rounded edges, which gave a feeling of tenseness when pinched. Round ligament normal. The gall-bladder was only found after prolonged search and careful dissection through the surrounding thickened, dense connective tissue. On pressure, the gall-bladder was found to contain fluid, but could not be emptied by pressure. No stone could be felt through the walls. On opening, it was found to contain about half a drachm of thick, creamy pus. On careful probing, a fine orifice was found, which traversed a band of adhesion uniting the tip of the bladder to the duodenum and of a length of about one-half inch, the probe entering the duodenum about one inch below the pyloric ring. The hepatic artery was normal in size and position, as was also the portal vein. The common bile-duct was at first mistaken for the portal vein, by reason of its size. On slitting up the common bile-duct its wall was found to be thickened, its cavity dilated to finger size or larger, and its mucous membrane thickened, rugous, and in places mammillated. The cystic duct appeared as a cul-de-sac branching from the common duct and resembling it in calibre, character of mucous membrane, and thickness of wall. No communication with the gall-bladder existed. There was no ulceration of the mucous membrane, which was studded with the enlarged orifices of glands. On following up the dilated common into the dilated hepatic duct the same increase of calibre was found. This distention was traced up throughout the branches in the liver, even in some places to the periphery of the organ, where they resembled the ends of glove-fingers. On slitting up one of the ducts in the liver it was found to open into a marble-sized pus cavity close to the surface of the liver, the pus contained being thick and pinkish. The liver section was granular, coarse, friable, and nutmeg in appearance; evidently fatty and cirrhotic.

Again, in the following case, No. VI., very similar, though even more aggravated, lesions were found.

Case VI.—I saw Dr. C. G. E., in consultation, in Binghamton, N. Y., on July 5, 1880. He was thirty years of age, and had enjoyed good health. His father and his younger brother had suffered from hepatic colic. He himself had been liable to such attacks for seven or eight years, but, after a trip to Europe five years ago, they seemed to have been arrested; but again, in the past three years, he had six or seven attacks. These apparently were attacks of catarrhal inflammation, with spasm of the bile-duct, but followed by very little organic change. On no occasion did they compel him to abandon his work. During the spring of 1880 he had been unusually busy, and had lost a good deal of rest. He was taken ill about the 14th of June with a chill, pain in the back, subsequent fever, and an intense pain in the region of the epigastrium and gall-bladder. Repeated hypodermic injections of morphine were needed to control the pain. There were several quite severe chills in the first thirty-six hours, with copious vomiting of bilious matter, while the temperature ran up after each chill to 105½°. He took calomel freely, in addition to the morphine; and later, when the tendency to return of chills showed itself, quinine was given in full doses. He continued to complain constantly of great pain about the gall-bladder. Vomiting ceased, but there was a tendency to hiccough. The temperature subsequently ranged from 102° to 103°. The tongue was heavily coated and dryish. There was a slight tinge of sallowness, but nothing amounting to marked jaundice. Examination showed an area of dulness in the region of the gall-bladder, extending three inches below the ribs. It was evidently not the distended gall-bladder, but appeared to be a partial enlargement of the right lobe of the liver, with matting of the adjacent tissues. It appeared indurated, and, on pressure, was very tender but without fluctuation. The fever was mark-

edly hectic in type, with tendency to profuse sweats at night. The urine was discolored and contained bile. The stools were brownish and even at times blackish, though probably from bismuth. The urine contained no albumin. The general liver dulness did not extend above the normal limit, nor did it extend uniformly below the margin of the ribs; but there was a very distinct semicircular area of greatly impaired resonance and increased resistance, with exquisite tenderness on pressure, which extended from the right nipple line to the median line, and from the lower margin of the ribs downward about two inches.

He did well from July 5th to July 11th, when there was a violent chill, followed by very high fever and cold sweat, leaving him much exhausted. There was still no decided jaundice. After this, he continued to have irregular chills with high fever.

I visited him again on July 24th. He was then extremely weak, with a glazed, dry tongue and thready, frequent pulse. The abdomen was distended. The area of dulness previously described was even more marked. There were decided hectic symptoms, though no distinct chill had occurred since July 12th. As the signs of internal suppuration were so clear, I proposed an exploratory puncture, which was agreed to. I introduced a medium sized trocar about half an inch below the margin of the ribs, in the region of the gall-bladder, and in a direction upward and backward to a depth of two and a half inches. However, nothing but a few drops of blood entered the vacuum. He died within a few days afterward, and the post-mortem examination showed that there was no gall-stone and no obstruction of the main bile duct. The gall-bladder was the seat of chronic inflammation; its walls were thickened and its cavity greatly contracted. It contained muco-purulent matter. There was marked circumscribed plastic peritonitis around it. The central portion of the liver was much enlarged, and extending upward into this area for a distance of several inches, and occupying a space of four inches in width, there were clustered around the lines of the bile-ducts numerous small abscesses. These varied in size from a pea to a hazel-nut. In some instances the abscess cavity connected directly with the bile-duct, and it seemed as though it might be a collection of pus in a dilated duct. More probably, however, the limiting wall was of morbid formation. The bile-ducts throughout the liver were distended, and there were a few small abscesses at distant points of the organ, near the capsule.

Without entering into the highly interesting questions of diagnosis connected with these cases, I may point out that, in the latter case, the manifest enlargement of the liver in the region of the gall-bladder called for exploratory puncture, although the symptoms had led me to expect disseminated miliary abscess, as indeed was found to exist. Did time permit, I would be glad to describe to you cases of uncomplicated purulent inflammation of the gall-bladder with similar fever, and also the more familiar type of case where a large calculus escapes from the gall-bladder by progressive ulceration, opening into the intestine. I have seen a number of cases of this kind attended with typical hepatic fever of great severity, lasting for many weeks, and yet terminating in recovery. In one such case, which I have published elsewhere, the patient died, years after, of pneumonia and the autopsy showed complete obliteration of the gall-bladder and cystic duct, so that the middle finger could be passed directly from the duodenum into the dilated ducts of the liver. The gall-stone was found in one of the pouches of the colon. In the following case, on the other hand, there is every reason to believe that the recurring attacks of angiocholitis resulted in the formation of a single large hepatic abscess. It is notable that, in connection with the violent outbreaks of fever, there was neither intense pain nor deep jaundice. It can scarcely be doubted, however, that the origin of the pus evacuated by stool was from the liver.

CASE VII.—A. B., aged forty-six, married, has been exposed to very bad air in the court room, and had also drank water freely from a dirty receptacle. Last spring and through the summer, had intestinal indigestion, with tendency to looseness of the bowels. This fall he assumed additional labor as professor in a law school. After great exhaustion and loss of sleep, was taken with fever; heavily coated tongue, foul breath; temperature 103° to 104°; urine heavily loaded, and contained some bile. No characteristic spots, no nose-bleeding or bronchial symptoms. The case ran a course for three weeks like an irregular typhoid. He was apparently improving, and his temperature was down when he had a chill while in bed and while still on liquid diet, so that there was no apparent cause. The temperature went up to 104½°. The following day it fell almost to normal, but rose again in the afternoon, and so on three successive days. At this time there was discomfort in the hepatic region. The urine contained more bile, and there was slight jaundice. He again improved, and the fever almost disappeared, but in two weeks there was a similar recurrence of chills with high temperature. He had taken abundant quinine from the beginning of the case until this time. There was a repetition of the same hepatic symptoms. After this there was again improvement, even more marked than formerly. At this time there was a mild attack of phlebitis of the right leg. After this he again improved, and for more than three weeks was free from fever; he began to sit up for several hours daily, and cautiously resumed solid food, when, on December 20th, after taking a greater variety of solid food than he had done before, he was again attacked with chills, the temperature going up to 104° and over, and recurring on three successive days, with similar hepatic symptoms. At no time had the tongue become clean or the breath sweet, though it was much improved before this last attack.

He had taken, with apparent advantage, cool water enemata of about one pint, at a temperature of 65°; but despite extreme care in every particular and the most judicious treatment, the attacks of fever recurred. I saw him in consultation with Drs. W. W. Johnston and Busey, of Washington, on December 23, 1889. For a few days subsequently the hepatic fever was intense, the chills occurred more than daily; the subsequent fever was very high (104° to 105°) and the sweats profuse. On Friday, the 27th, he was extremely feeble and ill, and the chilliness and sweating were almost constant. He had a strong call to stool and passed six ounces of offensive, decomposed pus. On Saturday night he passed eight ounces of the same material. Following

this discharge he made a gradual but complete recovery. The diagnosis of hepatic abscess in this case was supported by the exclusion, after repeated and searching examination, of any other source for the pus.

We have thus seen illustrations of various lesions in connection with which hepatic fever may present itself. We have also seen that similar lesions may exist without the production of this particular type of pyrexia. An attempt has been made to indicate some points of interest and importance in connection with the mechanism of its production. It has been assumed that this hepatic fever is not of very frequent occurrence, but although I may have happened to meet with a larger number of cases than should rightly fall to my lot, I am sure that it is not nearly so rare as has been represented. It seems important to place on record all carefully observed cases on account of the extreme difficulty in the differential diagnosis of the lesions, as well as in connection with the explanation of this type of fever and with the special conditions of the liver as regards its antiseptic secretion and its ptomaine-destroying function.

I will not attempt to speak fully to you of Weil's disease. This affection has only in the last few years been described as a separate entity; I do not think it comes properly at all under the class of cases I am describing. Everything connected with it seems to me to prove that it is a special infectious disease which requires much more close study in the hope of isolating the peculiar poison which produces it. The conclusions of all who have seen many cases are that it comes under the class of infectious fevers. It begins abruptly; it is attended with slight enlargement of the liver, and great enlargement of the spleen, and marked alteration of the blood. Between the fifth and seventh days the temperature falls, sometimes reaching the normal. About the tenth or twelfth day, there may be an accession of fever, though not a true relapse. There are characteristic pains in the limbs, especially in the calves, rendering motion intolerable. Jaundice is the most characteristic symptom. There is a difference of opinion as to whether the jaundice is from obstruction or alteration of the blood; my own judgment favors the latter view. There may be nephritic symptoms—albumin, tube-casts, and blood in the urine are common and very serious symptoms. Bronchitis, epistaxis, purpura, have all been observed as accidental complications. The disease has been observed in vigorous men of middle age; rarely in women and children.

One case, clearly to me of this nature, I find I have recorded in 1883 under the title of "acute infectious jaundice"—a name which I would at present suggest for this disease, until its nature is more accurately determined.

This occurred in the case of a travelling salesman, thirty-eight years of age, of muscular frame and excellent general health, whom I saw in consultation in the north-eastern part of Philadelphia, a healthy district. He had suffered from some malarial symptoms in previous years, but not recently, and during his last journey had not been in a malarial district. He had not been especially fatigued, and no reason could be assigned for the onset of the disease, which made its appearance immediately on his return to his home.

I found the patient, on the evening of the third day, with a temperature of 105°, with a wild, excited expression, injected eyes, wildly delirious, with a strong tendency to walk up and down the room, requiring the efforts of several men to restrain him. He complained of severe pain in the head and through the frame generally. He was already intensely jaundiced, the discoloration being peculiarly deep. This continued with increasing depth until his death, on the sixth day. He had already vomited several times; the stomach was non-retentive during the second day, but subsequently, with the deepening mental dulness, the stomach became quiet. The temperature sank to 102° on the third day, and continued to fall until toward death, when there was a rise again. The tongue was heavily coated, and soon became brown and dry. There were no pulmonary symptoms. The bowels were quiet, but responded to enemata. The spleen was distinctly swollen; the liver appeared normal in size. The pulse was rapid, 130, and this rapidity continued despite the deepening stupor and symptoms of blood-poisoning. The urine was not obtained until the end of the second day. It was then found albuminous, with epithelial and granular tube-casts. The amount secreted was small and intensely bile-stained. Death occurred in deep stupor, and was preceded by convulsive twitchings. The post-mortem examination showed no lesion of the brain; hypostatic congestion of the lungs; the spleen enlarged to double its size, very dark, and somewhat softened; the liver about normal in size, unusually dark, apparently very little, if at all, softened. Microscopic examination showed marked granular disintegration of many circumscribed areas of cells. The bile-ducts were pervious, and no obstruction was found to explain the jaundice. Of course, the mucous membrane may have been swollen during life, and the swelling have disappeared after death. There were no lesions of the intestinal glands; the kidneys were engorged with blood, and presented marked changes of infectious nephritis. The case was regarded as one of infectious disease of unknown type. Unfortunately, there were at that time no facilities for examining the blood and tissues carefully for microbes.

Clearly this acute infectious jaundice, which has close relations with *icterus gravis* of the older writers and of the present German school, has no relation whatever with the type of hepatic fever which I have described. It is connected in all probability with the entrance into the system of some specific infectious organism. I mention it to limit our field of discussion of hepatic fever more closely to the points I have proposed.

In conclusion: Although, as before stated, the term "hepatic fever" is more or less a misnomer, since there are various affections of the liver attended with other types of fever, yet there is a degree of usage which perhaps justifies retaining this name in connection with the particular paroxysmal fever I have described. It occurs at irregular intervals and is connected with angiocholitis, with more or less extensive occlusion of the ducts. At times there is no proof of the existence of pus or of septic action, although in the great majority of cases the pyrexia is associated with a purulent lesion at some point of the biliary canals. I will detain you but a moment to ask your attention to the analogy between these febrile attacks connected with the liver and "urethral fever," as it is often styled by surgeons. In doing so I will take the opportunity of referring to the admirable account of these two types of fever by Charcot, to whose instructive paper there

has been comparatively little of value added. We are all familiar with the sudden explosions of high fever, 103° to 105° F., usually preceded by a chill, which may occur in persons who have been subject to prolonged vesical or urethral irritation, and where the thickening of the mucous membrane and other coats of the urinary tract has occasioned more or less occlusion associated with the production of morbid discharges. For although urethral fever may occur without a previous morbid state of the urinary passages, it is far more apt to arise in connection with such lesions. The irritation caused by the passage of a catheter or the sudden development of complete occlusion at some point of the partially obstructed passages may, under such conditions, give rise to violent outbreaks of fever which are evidently strictly analogous with those we have studied under the name of "hepatic fever."

I must here bring these desultory remarks to a close, trusting that the imperfect record I have presented to you will be the means of eliciting, from the immense wealth of pathological material which this city contains, fuller contributions as to the frequency of hepatic fever and as to the various lesions with which it is most often associated. With such extended studies it is not too much to hope that the special conditions or agents which in certain cases determine its occurrence may be investigated with complete success.

ORIGINAL ARTICLES.

LABOR COMPLICATED BY A FIBROID TUMOR: CÆSAREAN SECTION.[1]

By JOSEPH S. GIBB, M.D.,
of Philadelphia.

The case here reported, though not positively unique, was deemed of sufficient importance to challenge a careful study. In a series of seventeen cases of the Cæsarean operation tabulated by Harris, there were five in which the operation was done because of a new growth obstructing the pelvic outlet. In three of these the tumor was fibroid; in one, cancer of the cervix; and in the fifth, tumor of the sacrum. Two mothers were saved and three lost. In but one was an attempt made to remove the growth at the time of operation.

The subject of this sketch, L. J., a primipara, aged thirty-five years, had always been in excellent health, never having been confined to bed. In April, 1889, she married, and two months thereafter found herself pregnant. During her pregnancy she enjoyed exceptionally good health.

Her labor began Friday, March 7, 1890, in the early morning. During the day the pains were slight and infrequent, and the underclothing was soiled by a discharge of fluid with each pain. Late in the evening the pains became aggravated and I was summoned and saw her for the first time. The uterine contractions at this time were slight and infrequent, perhaps at intervals of half an hour. Her general condition was excellent: she looked forward to her labor with no gloomy forebodings. Vaginal examination revealed a capacious pelvis. The progress of the finger in the vaginal canal was arrested by the presence of a large body which was apparently felt through the thinned-out uterine wall. The os could not be detected by the examining finger.

To my mind, at this time, it seemed as though some portion of the child was presenting, pushing down before it the thin uterine wall and the upper portion of the vagina, and displacing the os to a position back of the symphysis pubis and out of reach of the examining finger. Abdominal palpation revealed a peculiarly oblique position of the uterus and its contents. The head was evidently below and to the left, and in the abdominal cavity, whilst the extremities occupied the right hypochondriac region. The fœtal heart-sounds were heard with the most distinctness about two inches below the umbilicus, a little to the left of the median line.

As the uterine contractions were very infrequent, and being uncertain of my diagnosis, it was deemed advisable to wait until there was sufficient dilatation of the os to enable the examining finger to be introduced. The next morning the condition remained unchanged—if anything, the uterine contractions were less frequent. The os still occupied a position too high to be reached.

The patient was still very cheerful and engaged in slight domestic duties about her room.

The next morning (Sunday, March 9th), a more accurate diagnosis was possible. The uterine contractions had increased during the night. The os was found high up, back of the symphysis, somewhat, though not fully, dilated—sufficiently so, however, to enable the examining finger to detect the head. It was now apparent that the body above referred to was not part of the child, but a *tumor* in the pelvic cavity, diminishing its calibre to such a degree as to preclude the possibility of the head passing. This tumor occupied the posterior portion of the pelvic space, encroaching forward to within one or one and one-half inches of the symphysis pubis. It seemed firmly fixed in the pelvic outlet. The diagnosis, however, was still very difficult, in consequence of the high position of the os. So, in consultation with Dr. James Collins, it was decided to anæsthetize the patient to map out more fully the position of the growth, and then to do whatever might be considered necessary while she was in this state.

Accordingly, a consultation was held at 6 P. M., March 9th, at which were present Drs. Collins, Holmes and Longaker, and myself. After the patient was thoroughly anæsthetized it was apparent to all present that the growth was a solid or semi-solid tumor, situated between the uterus and rectum, and pushing the upper portion of the vagina down before it into the pelvic cavity. It was equally apparent, the tumor being fixed and immovable, that it would be impossible to draw the head through the narrowed pelvic outlet without great and irreparable damage.

In the judgment of those present the only course

[1] Read before the Northern Medical Association, February 14, 1890.

that presented was an immediate abdominal and uterine section. Accordingly, preparations were hurriedly made for the operation. Antiseptic and aseptic precautions were carried out, perhaps as fully as is possible in private houses in the humbler walks of life, and where little time is permitted for preparation. One vessel—a bowl—was reserved for cutting instruments; another for hæmostatic forceps, clips, etc.; still another for ligatures, sutures, and needles. The previously prepared antiseptic sponges were placed in a large basin. All these were covered with boiling water.

The abdominal wall was shaved to the pubes, thoroughly cleansed, first with soap and water, then with ether, and finally with a solution of bichloride of mercury, 1 to 1000. Towels soaked in the bichloride solution surrounded the seat of operation.

An incision was made in the abdominal wall, extending from an inch above the umbilicus downward to a length of 5½ inches, and rapidly carried down to the peritoneum. This membrane being incised to the same length as the abdominal wound revealed a uterus at full term, well and firmly contracted around its contents. The surface of the organ was seen to be covered with numerous tortuous veins. The uterine tissue seemed remarkably pale. A spot was selected at the upper portion of the body of the uterus and an opening sufficiently large to introduce a finger made with a scalpel and then rapidly extended to a length of 4 or 5 inches. The hand was immediately introduced into the organ and grasped the first presenting portion, which proved to be an arm; a foot was then grasped, the child turned and rapidly delivered. The child was asphyxiated and evidently suffering greatly from the prolonged compression to which it had been subjected; it was at once placed in the hands of Dr. Longaker, who after prolonged and skilful efforts succeeded in fully restoring it. Upon incising the uterus, and again after the delivery of the child, there was a gush of blood, but it did not seem to me greatly in excess of that of a normal labor. One fact remarked by all was the large amount of meconium in the uterine cavity—convincing evidence of the prolonged and ineffectual compression which the child had endured.

The placenta was attached a little to the left of the line of incision, and, almost immediately after the delivery of the child, appeared at the incision and was quickly delivered.

The uterus was now thoroughly freed from clots. Some difficulty was experienced in obtaining a complete and satisfactory contraction of the organ, but finally this was secured and the sutures were introduced.

The time occupied from the first incision to the introduction of the first stitch in the uterus was nine minutes. There were ten deep and about the same number of superficial Lembert stitches introduced.

After having secured the uterus from leakage the hand was passed into the abdominal cavity back of the uterus, and thence down into the pelvic cavity, to locate and, if possible, remove the growth which had caused the difficulty. The tumor was found to be a pedunculated fibroid, springing from the centre of the posterior surface of the body of the uterus by a short and thick pedicle, and occupying a position partly in the abdominal and partly in the pelvic cavities. Its position in the pelvic cavity was in the posterior (Douglas) cul-de-sac. It had pushed the vagina downward and forward and had compressed the rectum back toward the sacrum. All of the pelvic cavity was occupied by this growth save a space anteriorly of about 1 by 1½ inches. The growth had contracted firm adhesions in front to the uterus and vagina and posteriorly to the rectum. Laterally the adhesions were not so firm. Nevertheless it was immovable and fixed. It was deemed advisable to remove the growth, hence the adhesions were broken up with the finger, the tumor brought into the line of incision, the pedicle ligated, and the tumor removed. The bleeding from the torn adhesions was somewhat free, but not sufficiently so to demand ligatures. The abdominal and pelvic cavities were flushed with large quantities of hot water (which had been previously boiled) until the water returned uncolored. The cavities were then thoroughly sponged out until we felt assured there were no bleeding points left.

The abdominal wound was closed by eight or nine deep and four or five superficial stitches, a glass drainage-tube introduced into the pelvic cavity, the wound dressed in the usual antiseptic manner, and the patient put to bed and surrounded with hot bottles. The entire operation lasted one and one-half hours.

The patient's condition at the time of operation was far from satisfactory. Having suffered from irregular and ineffectual uterine contractions for sixty hours, she was worn out. The pulse was very rapid and weak. She took ether badly, requiring nearly half an hour for satisfactory anæsthetization.

Her condition otherwise was without incident until the uterus was incised; then there was sudden and alarming depression; the shock was so profound that she became pulseless at the wrist, and fears were entertained lest she might die before the operation was completed. However, upon the introduction of hot water into the peritoneal cavity, and the administration of digitalis and whiskey hypodermically, she rallied considerably. When she was placed in bed the pulse was still too rapid to count at wrist; the temperature under the tongue 94°.

The following is the record for the next ten hours: 10 P. M., pulse running, temperature 94°; 12 M., pulse running, temperature 94°; 5.30 A. M., pulse 150, temperature 95°; 7 A. M., pulse 150, temperature 98°.

For the first six or eight hours there was a profuse discharge of sero-sanguinolent fluid from the tube; the tube was cleansed and the fluid absorbed by means of antiseptic gauze every hour during this period. At the end of the first twenty-four hours there was very little staining of the gauze, hence the cleansing process was lengthened to every four or six hours. No nourishment or drink was given by the mouth, but to allay the burning thirst, and to promote recovery from shock, rectal injections of hot coffee were ordered every two hours. The vagina

was kept well cleansed by injections of boric acid. There was very little lochial discharge.

The patient did not rally in a satisfactory manner. During the first twenty-four hours there was constant retching and nausea, though no vomiting. By the evening of the first day the belly had become slightly distended and tympanitic, temperature rose to 100°, pulse still remained about 150 or 160.

The second day ushered in still more tympany, increase of nausea, and some vomiting; a feeble running pulse, temperature ranging from 100° to 101°; and marked evidence of peritonitis. Drachm doses of magnesium sulphate every hour, champagne, and rectal injections of turpentine were ordered. The magnesium and champagne were rejected, and throughout the entire day there was constant nausea and vomiting with few intervals of rest. The tube remained sweet and the discharge practically *nil*. By the end of the second twenty-four hours the tympany had increased to an alarming extent, and a rectal tube was introduced high up in the bowel, but with no relief. She continued to sink, and died at 5 A. M. on the morning of the third day, fifty-five hours after operation.

Autopsy (eleven hours after death).—Belly greatly distended and tympanitic; tube free from discharge and without odor; the abdominal wound had united below, but failed to unite above. The intestines were greatly distended with gas, gushing into the abdominal wound when stitches were cut. Evidences of an extensive peritonitis present. The omentum was bound to uterus by bands of lymph. The surface of the intestines was covered with a thin layer of recent lymph which bound them to the uterus and abdominal wall in front. Bands of lymph also bound the uterus in front to the abdominal wall, and posteriorly to rectum. There were evidences of considerable pelvic inflammation at the site of the torn adhesions. The incision in the uterus appeared about three and a half inches in length; the uterine wound seemed tight and secure, but on cutting stitches it was found that no union had taken place. The *internal or mucous coat of uterus was in a sloughing condition* and covered with dark-gray secretion. In some places the mucous membrane was entirely denuded, showing the muscular coat.

The site of the pedicle was seen to be in the centre of the body of uterus posteriorly. Both ovaries were cystic. There was little or no fluid, either serous or purulent, in the pelvic cavity. The kidneys were congested, though otherwise healthy.

In reviewing this case there are many features worthy of consideration. I desire, however, to submit but a few for discussion.

There can be no question as to the necessity for the Cæsarean operation. Here was an immovable, fixed tumor filling up the pelvic cavity and diminishing its calibre to such a degree as to leave but one or one and a half inches of available space through which the child could pass.

Granting then the necessity for, and the wisdom of, our course, the first feature that suggests itself is: Did we err in deferring the operation to so late a period? Would the chances for success have been increased had we operated Friday night, twelve hours after the commencement of labor? It was stated in the notes of the case that after the uterus was incised it was found to contain a large quantity of meconium; again, at the autopsy, we found the uterine mucosa in a sloughing condition. The first condition noted is, except perhaps in breech presentations, indisputable evidence of the powerful contraction of the uterine muscle; the second condition is likewise evidence of the ill effects of these prolonged and ineffectual contractions.

In the series of cases tabulated by Harris[1] we find that nine women recovered. Of these, four were operated upon before the advent of labor; one just as labor had begun; two in ten and twelve hours respectively, and there are but two successful cases where the operation was deferred a longer period.

In the light of the autopsy and in the face of statistics of favorable cases, we are forced to but one conclusion, viz., that the chances of a favorable result would have been immeasurably increased by an earlier operation. To have the best possible conditions we should have known of the existence of the growth previous to the labor. This would have given ample time for preparation. The hurry and flurry of arrangements for the operation, with its consequent ill effects on the *morale* of the patient, would have been avoided. The condition of the uterus, as revealed at the autopsy, would not have occurred: and last, but by no means least, our patient would not have been worn out by the hours of suffering from ineffectual labor.

This case stands as an admirable example of the necessity for the examination, both vaginal and abdominal, of our obstetric cases previous to labor.

In justification of the delay of about forty-eight hours, which was the period of time from my first visit to the time of operation, I would call attention to the notes of the case, and candidly confess that I would be unable to do differently should a similar case occur. The character of the contractions deceived me. It was not apparent that labor was really in active progress for at least thirty-six hours after my first visit.

As to the diagnosis of the tumor, such I believe was absolutely impossible without the administration of an anæsthetic; and believing as I did, that the body felt was a portion of the child, there was no reason for such administration, as the child had not engaged, nor were the contractions or the condition of the patient at this time sufficient to warrant it. However, I am firmly convinced that where there is the least element of doubt in our diagnosis we should

[1] Harris: American Journal of the Medical Sciences, February, 1890, p. 118.

use every means at our command to clear up this doubt, even to the administration of an anæsthetic.

The second proposition I have to offer is: Would a supra-vaginal hysterectomy (Porro operation) have given us a better chance for success?

The autopsy disclosed a uterine mucosa in a sloughing condition, which, in our opinion, had much to do with the fatal result. The operation spoken of would have effectually removed this source of infection. On the other hand, a Porro operation would have consumed much more time and added greatly to the condition of shock.

It is to be remembered that when the uterus was incised there was an alarming depression from which our patient rallied very slowly.

In our judgment a supra-vaginal hysterectomy would in no wise have averted the unfortunate result; on the contrary, it would have probably hastened it.

The third and last proposition: Was it an error of judgment to remove the growth in view of the exhausted condition of the patient?

After mapping out the position of the tumor, and being fully assured that the adhesions were not so extensive or firm that they could not be readily broken up with the finger, the temptation to remove it at this time was almost irresistible.

So far as the element of time is concerned, this could have had but little influence, for the removal of the growth occupied not more than five or ten minutes.

As regards the tearing of the adhesions and the subsequent inflammatory condition, the autopsy disclosed marked evidences of pelvic inflammation at the site of the torn adhesions. I am not convinced that the removal of the growth, and the resulting inflammatory condition, may not have added to the elements which brought about the fatal result.[1]

817 FRANKLIN STREET.

NOTE ON THE USE OF ESERINE IN ULCERS OF THE CORNEA.

BY G. E. DE SCHWEINITZ, M.D.,
OPHTHALMIC SURGEON TO THE PHILADELPHIA AND CHILDREN'S HOSPITALS.

IN THE MEDICAL NEWS of March 8, 1890, Dr. H. F. Hansell records the results of some clinical observations on the treatment of abscess and deep ulcers of the cornea, and concludes that eserine is superior to atropine. While far from willing to discontinue the use of atropine, my experience, in selected cases, especially in the wards of the Philadelphia Hospital, is in exact accord with that given by Dr. Hansell. In patients of generally feeble powers, especially if past middle life, and if the lesion is situated in the periphery of the cornea, eserine acts more favorably than atropine. Whether this action depends upon its property of lowering tension, provided the intraocular tension is increased at the time of its application, or upon its asserted power of checking the migration of white blood-corpuscles, or because it contracts the pupil, enlarges the surface of the iris, and dilates the ciliary arteries, has not been definitely settled. The clinical fact remains that it has the power of limiting the sloughing process, and in the opinion of Brudenell Carter is "the most potent medicinal agent for the fulfilment" of this indication, having "been the means of saving numbers of eyes which, without it, must have perished."

Hospital case, a male, aged fifty-five, in feeble general health. A ragged ulcer, with unhealthy edges, was situated at the upper and inner border of the cornea, marking the position of what previously had been an abscess with elevated surface. The treatment comprised atropine, boric acid solution, not compresses, and tonics. The process was unchecked, and each day the appearance was more unfavorable. All remedies were discontinued and eserine solution substituted for them. The effect was almost immediate, and within ten days firm cicatrization had taken place. At no time was there photophobia. The patient had some brow pain.

This case is worthy of record because the cure may be ascribed entirely to the eserine. Other remedies had failed and this drug was employed to the exclusion of hot compresses and antiseptic lotions, the almost universal use of which, in the opinion of Mr. Nettleship, "renders it difficult to draw trustworthy conclusions as to the effect of eserine." If there is iritis, eserine, as a rule, is not advisable; but the mere presence of posterior synechiæ, the result of former inflammation of the iris, does not contraindicate the remedy.

Hospital patient, male, aged twenty-five, with irregular pupils, the result of iritic adhesions, presented himself on account of a large sloughing ulcer of the right cornea. The cause of the ulcer could not be ascertained (the patient spoke Russian only). The usual atropine treatment was not efficacious, while under the influence of eserine cure resulted. After cicatrization was complete, atropine locally, together with mercury and iodide of potassium, was ordered, with marked benefit to the old iritis. In this case, however, hot compresses and stimulation of the ulcer were also employed.

Dr. Hansell considers solutions of eserine stronger than two grains to the fluidounce inadvisable; Carter has suggested four grains to the ounce. My experience is limited to weaker solutions, one fourth to one grain to the ounce; in this way one of the

[1] The child weighed at birth nine pounds full. At this day, the thirteenth from birth, it remains strong and vigorous. The uterine fibroid weighed two pounds.

objectionable symptoms following the use of the drug—headache—is reduced to a minimum. Operative procedures, in the opinion of Dr. Hansell, should be limited to a division of the anterior surface of the abscess and evacuation of the pus. My own preference in open and sloughing ulcers is for the actual cautery. This may be used, if necessary, after division of the anterior surface of an abscess. I have employed this method in many cases and in various types of corneal ulcers with uniform success; in a number of instances of decided hypopyon-keratitis, complete absorption of the pus has followed a thorough application of the thermo-cautery. Dr. Hansell's protest against the common habit of prescribing cocaine in abscess of the cornea and other severe inflammations of this membrane, an injudicious method of practice ably condemned by the publication of Jackson, of this city, deserves emphasis.

MEDICAL EXPERT TESTIMONY AND ITS ADMISSIBILITY.

By E. SPENCER MILLER,
OF THE PHILADELPHIA BAR.

The profession is so frequently called upon to testify on medical subjects in courts of law, that it has become quite important for the physician to know what are the essentials of legal competency to speak as an expert witness.

One is constantly surprised to find that subjects of every-day familiarity are yet, in science, topics of hot discussion. The question as to what extent of experience entitles a man to be heard as a medical expert witness, appears to be one of these vexed subjects.

A case decided by the Supreme Court of Wisconsin upward of a year since, and officially reported a few months ago, brings up this question in a most striking way. A report of this case appeared in the *American Law Register* for August, 1889, together with a very full annotation—citing precedents throughout the country—by Robert G. Morrison, of Minneapolis, Minn.

A prisoner, already committed to the State prison to serve a life sentence under conviction of murder in the first degree committed by arsenical poisoning, was relieved of his term of imprisonment, and, by an extension of the legal principle which generally forbids a second trial in capital cases, was set at large to live out his days scot free, only because the jury upon whose verdict his sentence was pronounced had been allowed to hear the testimony of two doctors who in their practice had never had actual experience in cases of irritant poisoning.

John P. Soquet was put on trial in April, 1888, for the murder of his wife, which was committed fifteen years before. Prior to 1873 he had lived with his wife and their seven children upon a farm in Brown County, Wisconsin. August Mainsort and his wife lived a mile away. It seemed that criminal intimacy existed in June, 1873, between Soquet and Mainsort's wife. Soon Mainsort suddenly died. Soquet assumed direction of his burial, and showed much zeal in hastening the ceremony. Before burial an inquest showed a quantity of arsenic in the dead man's stomach. A few days later Soquet's wife died, and the survivors seized the auspicious moment to wed each other. The wife's death had occurred under circumstances casting very strong suspicion upon Soquet. The physician attending her had diagnosed the symptoms as those of corrosive poisoning, and then, apparently suspecting foul play, had withdrawn his services. In the course of the trial this physician was called to describe the occurrences and prove the cause of death. He was asked: "What are the symptoms of arsenical poisoning?" Before an answer was permitted he was questioned as to his knowledge and experience. It appeared that he had been for ten years a member of a medical society and had practised twenty-five or thirty years. No case of poisoning, however, had come before him. He had only studied that branch of practice in common with others. Against the protest of counsel for the accused, this doctor was then allowed to state the symptoms of arsenical poisoning. As specified by him they tallied closely with those observed in Soquet's wife. Upon further questions in cross-examination, the witness said he had never seen a death from irritant poisoning—knew the symptoms only from "theory," his "knowledge as a student of medicine," and from books—without practical observation. Another doctor, with still less general knowledge, and with no actual experience in cases of poisoning, was called in corroboration. Upon a description of the symptoms observed he diagnosed the case as indicating arsenical poisoning. Two other physicians, who had had actual experience in the treatment of arsenical poisoning, testified, and their statements were to the same effect.

The jury found Soquet guilty, and the court pronounced sentence of imprisonment for life. On appeal the Supreme Court reversed the decision. As above indicated, this action sent him back to liberty, and, we may infer, to the embraces of his blood-bought consort. The national constitution prohibits putting a person accused of murder to the jeopardy of trial more than once.

The reasoning of the Supreme Court in the course of its opinion goes very far, much further than was necessary to justify a reversal of the judgment.

Judge Orton, who delivered the opinion of the court, relied upon the reasoning and authority of a

prior case (Boyle *vs.* State), wherein a somewhat different question was decided.

It was there held that a witness cannot testify to the published statements of an author upon a question of medical science.

After referring to the well-established doctrine that a medical book itself cannot be offered in evidence, he quotes from the opinion of the court in Boyle *vs.* State as follows: "Certainly, if the book itself cannot be read in evidence to the jury. the witness cannot be permitted to give extracts from it as evidence, depending upon his memory for their correctness," etc. Judge Orton then proceeds: "The testimony of such medical witnesses is at least hearsay—what medical books and teachers taught or told them, repeated from memory. The learned counsel for the State asks this court to review and overrule that case as not supported by authority." But it is supported by authority and equally by reason.

Perhaps it would have been wiser if the counsel for the prosecution had argued that the two cases were very different. The weight of authority is *with* Boyle *vs.* State, but *against* Soquet *vs.* State. That the decision in Soquet *vs.* State is in conflict with the current of decisions in this country and in England is very clearly shown by Mr. Morrison's notes. We propose to present the principles which thus appear to be established and the reasons for them.

At the foundation of the jury system lies the theory that the object to be sought is such a decision of the litigated question as the *judgment of the people at large would affirm.* This is the key-note of our whole structure of government. The Constitution of the nation and that of every State are the formulated will of the respective peoples. The subordinate law, too, whether written or unwritten, is the work of the people through the medium of legislative representatives or judges whom the people select. Hence no more appropriate body could be found to decide questions which arise in carrying into practical effect the laws thus sprung from the people, than one taken from and quite in accord with the great body of the people. The same theory, worked out to its logical conclusion, will harmonize and show the basis of almost every rule of evidence.

The assumption is, proceeding from the theory above stated, that the combined judgment upon all non-legal questions of a group of men—as great in size as may be, consistently with convenience and wieldy proportions—taken from the mass of the people by lot, and so, in some degree, representative of the whole body of citizens, will produce a result more likely to satisfy the public mind, and, indeed, more likely to be just, than the verdict of any other practicable tribunal.

Upon this view the system depends, in a large measure, for its justification, and practical test vindicates its theory. As long as this method of trial does not tend to gross miscarriage of justice, perhaps the object of securing the people's confidence in the issues of legal proceedings, is more important than that of attaining the greatest correctness in the matter of sifting testimony.

In general, the system requires that all evidence be confined to the narration of primary facts observed through the senses of the witness. His opinion upon matters as to which common judgment applies, cannot be received, because to accept it would be to forego in some degree the fruit of a popular decision. The object is to obtain the opinion of the *jury*, and if litigant parties may, at their will, present to the jury for their guidance the judgment of other persons, the benefits of the system are endangered.

In most cases before a jury, however, questions arise as to which popular knowledge is inadequate. It would, in such cases, be absurd to deny a jury all light save the mere narration of facts observed through the external senses. Where the issue is what percentage of metal a certain lode in a given ore-bed will yield; whether a specified plan of bridge structure, with members of a particular size, will bear burdens of a required weight; what is the value of a certain remote tract of wild lands; whether a peculiar observed state of the stomach and intestines indicates poisoning, and if so, what agent: in all such cases it would be extravagant to confine the testimony adduced to a mere narration of facts noted by external senses of the witness. No man would be satisfied with such data if the matter came up for consideration in his personal affairs, and therefore, when, in performance of a public duty, he deals with the interests and, perhaps, the life of another, a due solicitude requires that he should have further aid. If, then, this be the general view regarding such matters, the fundamental principle of the jury system requires that it should be applied in the trial of causes. Otherwise the jury's verdict could not represent what would be the popular judgment.

A few other exceptions exist to the rule that opinions are inadmissible, but it is unnecessary to refer to them at present.

The next question is: "How shall it be decided what matters thus call for expert opinions and what must fall under the general rule which rejects testimony in such a shape?" To find an answer we fall back upon the fundamental principle that the jury's verdict owes its value to the fact that it is supposed to be an exponent of that which would be the popular judgment. When any point arises, in a trial, which belongs to a plane of study or experience commonly recognized as quite above the general level of information, opinion-testimony upon that

point is admissible. If a man of ordinary prudence would defer action upon such a question, were it to arise in his own affairs, until he had taken the opinion of one having special acquirements on the subject, then the jury may have the like aid. Some assistance is afforded in the application of this test by the fact that, in those subjects as to which deficiency of popular comprehension is generally recognized, the demand for advice or services from persons specially qualified is likely to give rise to a class of individuals trained to answer the demand. Hence, when the inquiry before a jury raises a question belonging to some sphere which is assigned to a thoroughly recognized vocation marked by the necessity of special training for it, then the opinion of a competent person upon that question is generally admissible. In this view the test of admissibility of opinion-evidence is sometimes stated to be that such testimony is competent only where the considerations appertaining to the point to be proved belong to the dominion of a recognized vocation exacting a particular learning or experience.

The remaining point to be considered is: What should be required—where a question calling for expert testimony has arisen—of a witness who is presented to give his opinion as evidence? What is an expert?

This is the point which came up in the case of Soquet *vs.* State.

What indication is to be drawn from the fundamental consideration which was stated? Following the reasoning heretofore used, the person offered must be one of so great proficiency that a prudent man, where his own affairs are involved, would be satisfied to accept such guidance.

It might reasonably be said here: "Why not let the jury decide whose opinion they will hear?" "If the design be to arrive at what would be the popular judgment, by submitting the case to a body of men taken as representative of the people, will not the conclusion of that body upon the degree and character of proficiency in any science, needful to make a man's opinion worthy of credit, be the truest guide?" The same argument might be urged as to every other question regarding the admission of evidence. An answer is quite obvious. Were the popular judgment actually taken upon a question, the conclusion reached would be, in some measure, the result of guidance by a comparatively few individuals of peculiarly strong mental grasp and power of influence. The views of these persons would sway the minds of their weaker fellows. Owing to the necessary limitation in number of the jury panel, it must frequently happen that no such person is to be found in the jury. In no point would the influence of such persons be more needed than in deciding just such questions as those which we are now considering. Since they must, as has been said, be frequently lacking, the decision of these problems is assumed by the court. The degree of capacity needful to judge of the veracity of a witness, the probability or improbability of narrated facts, is very much below that competent to limit correctly the province of opinion-evidence. Moreover, it results necessarily from this same limitation of numbers, that the process of decision will not have that character of composition out of the elements of all individual and factional tendencies, which popular arbitration, applied under absolute conditions, would afford. It is further to be noticed that practical considerations, such as the necessity of limiting the time to be consumed by a litigant in the presentation of his case, claim attention. The patience of a jury might serve to hear very many witnesses whose competency is so slender as to give but little satisfaction. Economy requires that a litigant should present such a class of witnesses as will speedily afford a good weight of authority, and a judge who, unlike a jury which is empanelled for but a single case, is charged with responsibility for the prompt disposition of business throughout the entire term of court, is a better dependence for regulating matters of despatch.

We have thus reached a general understanding of the tests which rule the admission of expert testimony. Whenever a question of fact arises before a jury, involving considerations generally recognized as out of the sphere of common information, expert evidence is admissible to furnish light upon these considerations. Upon such questions, opinion-evidence may be received from any person whose acquirements are such as would satisfy the public in general to act upon his or her conclusions as to matters of personal importance to themselves.

A practical point may here be called to attention.

When the law attempts to discriminate between persons whose attainments in a certain direction constitute their capital and stock in trade, it stands upon delicate and difficult ground. This is especially so when the vocation is one of those often regarded as particularly elevated and dignified, which are known as the learned professions. Hence there is a very noticeable tendency in the decisions, to admit the testimony of persons generally where they are well recognized as belonging to any such peculiarly learned or skilled body—so long as that repute is not held by deception or artifice—without making a close inquiry into the extent and frequency of their experience or research.

Let the tests which have thus been arrived at be now applied to the case in point.

No question appears to have been raised whether the point involved in Soquet *vs.* State was one calling for expert evidence. Under the principles which have been stated, there was no room for doubt that such evidence was admissible. The

only doubt was whether the two physicians who had never seen cases of irritant poisoning could properly be allowed to tell the jury what the symptoms of such a disorder are.

It can hardly be contended that the public in general give credit to only the results of personal experience by that physician from whose mouth they receive the opinion. Most persons would prefer a judgment formed from general familiarity with and comparison of those records of the experience had by other men whose intelligence and innumerable opportunities for observation made them famous, than that of a man whose information is only empirical. No doubt much immediate observation of like cases, by the practitioner whose advice may be received, is important, but—certainly upon such a point as the signs of any given poisoning agent—a general knowledge of the authorities would seem to be more essential. It must often be unsafe to rely upon observation of other cases. Individual peculiarities of the patient must often cause a variation of external indications. Observation of outward aspects may not deduce the essential features of that condition which is their cause, and so may give little aid to the practitioner. The books, on the other hand, will state both the probable range of variety in the symptoms, and the character of that radical disturbance of which the symptoms are exponents. Moreover, physicians who have not had actual personal experience in just that disorder whose symptoms they are called upon to describe, are not necessarily quite without such aid to their theory as comes from immediate observation. Experience in more or less different cases must throw side-lights which will afford much service. A multitude of analogies and similarities exist, which tend to make one line of experience furnish a valuable aid to quite different practice.

No doubt a father who seeks medical advice for his child in dangerous illness would much prefer to employ a physician who adds actual experience to book-study of the disease to be treated. But this is not the question. There is no rule of evidence which excludes a witness merely because a person *likely to enlist more confidence* can be found. It is enough that people in general would give weight to the views of such a one for guidance in matters of importance to themselves.

It would, therefore, seem that, in order to justify the view laid down at the beginning of this paper—that the established precedents are adverse to Soquet *vs.* State, it is unnecessary to draw into the reasoning that practical—somewhat illogical—point of the law's unwillingness to discriminate in point of competency between members of a learned profession.

The reasoning of the court, of which the chief part is above quoted, seems very far from persuasive. There are many reasons why a medical book should not be put in evidence by giving it to the jury to read or by reading it to them. There is danger of the author's meaning being misunderstood. No opportunity is furnished the adversary for ascertaining by cross-examination just how his language is to be taken. In almost every book, probably, passages are to be found which would seem to be contradictory of each other. Either one, if taken alone, would probably convey a misleading idea. Perhaps a perusal of the whole book will be necessary before some of the passages contained in it can be thoroughly understood. Hence it would be quite unsafe to allow an extract to be read to the jury.

No doubt it follows, as the court says, that the recollection of any person, whether physician or not, upon some extract from a certain specific author, would be inadmissible. It is quite another and unjustifiable thing to hold that the product, in a mind specially trained and cultivated in the subject, of a personal study including not only the book in question but the books of others upon the same or kindred subjects, is not admissible.

The deduction which we have attempted to make from very radical principles of law, leads, therefore, to these results:

I. Expert opinions are not admissible, except where the point in question is plainly out of the range of general information.

II. When matters of this sort arise in courts of law no person will be admitted so to give his opinion unless his training has been such as would lead the public in general to rely upon his judgment as to like matters.

III. The law does not judge of expert admissibility upon the basis of any specific opportunity or opportunities had by the witness for acquiring knowledge of the particular point arising. It will neither admit a person as an expert witness upon a mere showing of occasion in his experience for acquiring knowledge upon the particular point in question, nor will it exclude one who shows assuring general familiarity with the branch of knowledge concerned simply upon the ground that his experience has not included any case presenting the same facts as that before the court.

CLINICAL MEMORANDA.

OBSTETRICAL.

Face Presentation, complicated by a Spinal Tumor; Craniotomy.—The patient, aged twenty-six, was a primipara, small, but well developed, born in America. On November 3d, 6 A. M., I found her in labor. Upon examining her abdomen, I noticed a peculiar peaked or dome-shaped appearance in the hypogastric region. It felt hard and hemispherical, and conveyed the impression

that it might be the fœtal head. The heart-sounds could be heard most distinctly below the umbilicus a little to the right of the median line. A twin pregnancy was suspected, but a second heart-sound could not be detected. The mother of the patient said that she had noticed this peculiar projection several months before. That I had to deal with a monstrosity or a spina bifida was to me the most plausible explanation. Upon examination the os was found to be dilated sufficiently to admit two fingers, revealing a full face presentation. In fact, the extension was so extreme that the forehead was pushed behind the symphysis pubis, and the chin pointed to the coccyx. (Fig. 1.)

Fig. 1

Various methods for reducing the extended head were resorted to, but without avail. Version was attempted, but likewise failed. The patient being now considerably exhausted, and the uterine forces flagging, the forceps were applied, and the forehead was forced from behind the symphysis pubis to bring the brow in position for craniotomy. Smellie's perforator was used, and great difficulty was experienced in preventing injury of the maternal parts, as they were much swollen from the pressure of the head and the prolonged manipulation. The head was delivered, and prompt expulsion of the child was looked for. With all the physical force which could be applied with safety to the mother, and without pulling the child to pieces, it could not be delivered. The arms were brought outside, but without any appreciable effect. Evisceration was next resorted to, but this did not diminish the bulk sufficiently to admit the hand or fingers for exploration. Dr. Joseph Price's crushing-forceps were applied to the pelvis of the child with telling effect. With the assistance of Drs. M. and J. Price, I worked for nearly four hours, when the child was finally delivered.

The combined force of the crushing and powerful traction burst the tumor into the abdominal cavity of the child, and thus the bulk was diminished. The skin covering the tumor was stripped off by the pubis.

It is a question in my mind whether Cæsarean section would not be a safer procedure in cases such as just described. At one time, when delivery seemed utterly hopeless, Cæsarean section was thought of, but, as her injuries were already so great, and her condition so bad, she could not have survived such a procedure. A large abscess formed in the vagina. Three weeks later she had recovered.

The child was a male, weighing about five pounds, poorly nourished, and with a club-foot. The sacro-lumbar region presented an oval, slightly lobulated tumor larger than a child's head. The tumor felt doughy to the touch, with here and there a fluctuating point. The skin was neither discolored nor adherent, except at a point over the middle of the growth, where there was a dimpled adherent point resembling the umbilicus. An incision in the median line through the skin, superficial fascia, and fibres of the gluteal muscles disclosed the much thickened coverings of the spinal cord.

Fig. 2.

About three ounces of a clear fluid, apparently cerebro-spinal, escaped from the sac. The defect in the spinal column consisted of the entire absence of the fourth and fifth lumbar vertebræ, sacrum, and coccyx. About one-fifth of the tumor extended into the abdominal cavity

through the bony defect. The cord appeared normal above the seat of the growth.

The microscopical appearance, as described by Dr. Morris Booth Miller, was as follows: "Very small multinuclear cells, round, of uniform size, with no interstitial matter whatsoever. The general character of these cells approaches that of embryonal epithelium more than any other structure. There are no cells of a sarcomatous nature."

This case presents sources of perplexity hard to overcome. The only logical conclusion which can be drawn from the position of epithelioid cells within the meningeal coverings of the spinal cord is, that the source of these cells is the central canal of the spinal cord. Proliferation of the epithelial cells of the spinal canal is described by Ross in his *Diseases of the Nervous System*, under the head of Periependymal Myelitis or Syringo-myelitis. Speaking of the morbid anatomy of this affection, he says:

"In periependymal myelitis the epithelioid cells which form the lining membrane of the central canal, and the cells of the neuroglia which surround it, undergo proliferation, so that the central gray column becomes altered in structure. In some cases the tissue appears to consist chiefly of epithelioid cells which are irregularly polyhedral in form, and which may be pressed closely against one another, or separated by a variable quantity of amorphous material."

He goes on to say that this morbid process is usually found in the cervical cord, and that the enlargement of the central canal rarely exceeds the dimension of the finger. He does not mention the occurrence of congenital syringo-myelia.

It would be plausible to suppose that the absence of neuroglia cells in the case was due to the fact that the rapid growth of the epithelial cells outran that of the neuroglia proliferation, and that the remains of the spinal cord might be found along the sides of the tumor in thin layers.

John S. Miller, M.D.
Philadelphia.

HOSPITAL NOTES.

DOUBLE HYDROCELE. CHRONIC ABSCESS OF THE FEMUR. RADICAL CURE OF INGUINAL HERNIA.

Abstract of a Clinical Lecture delivered at the Roosevelt Hospital, New York.

By CHARLES McBURNEY, M.D.,
ATTENDING SURGEON.

Case I.—This case is interesting both on account of the history and on account of the shape and tension of the tumors. The man states that about one year ago he first noticed an enlargement on the right side of the scrotum, which he is positive disappeared entirely after using some liniment. The swelling returned about four months ago, and since then the other side has swollen. One tumor has already been punctured, and its fluid contents removed, but at present the sac is again greatly distended with fluid. The tumors are translucent and perfectly irreducible, and it is fair to suppose that we have to deal with one of the ordinary forms of hydrocele, *i. e.*, of the tunica vaginalis. The shape is different from that of most hydroceles, the tumor passing well up into the canal, and being very tense and feeling solid at the lower portion. The constrictions which give these tumors their peculiar aspect are due to thickened sac wall at these points. It is probable we shall find that the testis lies within the sac in both cases. The operation which has been selected is known as Volkmann's operation, and consists in incising the sac and stitching the edge of the skin to the cut edge of the serous membrane so as to provide against primary union, and to obtain complete closure of the sac by adhesion from within. This operation was chosen in the present instance in preference to the methods by injection of iodine or carbolic acid, which are both excellent methods, because this patient is a working man and is anxious to be radically cured without danger of recurrence. It is probable that he will be cured in about two weeks.

A straight incision was made over the right sac through all the tissues, and as a precaution against wounding the testis the opening in the sac was first made at the upper part, so that the finger could be introduced and the exact position of the testis determined. The fluid in the sac was under such great pressure that it was forced out through the opening for a distance of one or two feet. The right tumor proved to be an ordinary hydrocele with the testis somewhat enlarged, and with one or two points of adhesion. The left sac was similarly treated, and the testis was found adherent to the anterior wall immediately in the line of the lower portion of the incision. Dr. McBurney remarked that if the precaution of opening the upper part of the sac first had not been taken, the testis would have been split open by the knife, an accident that he had once witnessed during the performance of this operation. This sac ran into the inguinal canal as far as the internal ring. Having completed the suturing of the serous membrane to the skin, the cavities were irrigated with Thiersch's boro-salicylic solution, drainage tubes introduced, and the wound dressed with powdered iodoform and a packing of iodoform gauze. Iodoform gauze compresses over this—protected from possible soiling by rubber tissue—were applied, and the whole secured by a spica bandage. The tube should be removed in three days, and after this the packing changed on alternate days.

Case II.—The attention of the class was next invited to an interesting case of bone disease, which in its insidious development, and uniform enlargement of the whole of the affected bone, resembled quite closely certain cases of a very subacute form of osteomyelitis resulting in the formation of pus.

The patient, twenty one years old, stated that one year ago, after some exposure, he felt pain in the lower and inner side of the right thigh, which was unattended by chill, fever, or any special illness. He received hospital treatment consisting of various external applications for about three months, during which time no sinuses appeared. There had been only slight disability and he came to the hospital chiefly on account of a fluctuating swelling on the outer side of the thigh. The whole lower half of the thigh was found to be at least one-third larger than the other portion. There was a general enlargement of the lower half of the shaft of the femur, and, on the outer side, a fluctuating swelling

which upon manipulation discharged, for the first time, a few drops of pus.

After applying a constrictor to the limb, the sinus was explored and found to lead to a sac of considerable size filled with tuberculous-looking granulations. The sac was laid open, and at its extreme lower end there was a minute opening passing directly backward against the shaft of the femur, a considerable distance from the superficial portion. A part of the bone was bare, and the probe passed directly into the shaft for some distance. This condition of affairs indicated a slowly forming bone abscess. A long, thin sequestrum was next removed. Leading from the first cavity was a sinus extending up to the anterior portion of the femur, although there has been no apparent suppuration in this part of the bone. The disease has extended into the epiphysis of the femur, and the fingers, reaching down close to the cartilage, still detected diseased tissue. There was also a cavity in the soft parts in the popliteal space communicating with bone, and filled with soft granulations. It extended within one-quarter of an inch of the surface on the inner aspect of the femur. This was also laid open. The limb was kept elevated while the Esmarch bandage was being removed. Two points bled freely, and as they were too close to the bone to be properly secured by ligatures, it was decided to leave the clamps *in situ* for two days. The wound was necessarily a very extensive one, and after packing it with iodoform gauze and putting on the usual antiseptic dressing, a wooden posterior splint with a footboard was applied.

Case III.—A man, twenty-five years of age, was the subject of the next operation. He had had an inguinal hernia on the right side for five years. It had given him considerable pain and inconvenience and a truss was quite painful. The patient was in good condition; the hernial mass and ring were comparatively small so that the canal had not been much distended, the hernia coming half-way into the scrotum and emerging away from the external abdominal ring, and the hernia was easily reduced, so that the case is a favorable one.

Dr. McBurney said that he would perform his usual operation, which consists in cutting down on the sac, opening the canal, ligating the sac at the level of the internal abdominal ring, and afterward so treating the wound by sutures and packing as to keep it open during the whole process of healing, with the exception of the part occupied by the spermatic cord.

The pillars of the ring were readily exposed, and the anterior wall of the canal found to be very weak. In order to facilitate the handling of the sac, the canal was next opened, thereby exposing a small hydrocele of the cord, behind which was the hernia. The hydrocele was treated by splitting it open completely. The next step was to separate the cord from the sac, which is always comparatively easy in the canal, but sometimes exceedingly difficult lower down. Dr. McBurney said that the success of this operation depended entirely upon the absolute and complete removal of the entire sac, and he had no faith in any operation that did not contemplate this. The sac was separated from the cord up to the internal abdominal ring, and until it was possible to apply a ligature on a level with the peritoneum. The sac was next opened, a portion of omentum ligated, and the stump returned to the abdominal cavity. In applying a ligature to the stump, it is not applied very tightly—only enough to stop the bleeding, and not enough to injure the soft vessels and give rise to secondary hæmorrhage. After the stump was reduced the sac was pulled down so as to "take up the slack" in the peritoneum, and while held vertically, the operator's finger was introduced into the sac to make sure that there was no intestine within. While the finger was still in this position, the assistant tightened the ligature at the highest possible point. The sac when cut away was almost as thin as a cobweb, and, therefore, useless as a pad or plug to prevent the return of the hernia. Several stout sutures were then introduced so as to bind together the tissues forming the upper wall of the wound, and a similar series of stitches held together the tissues forming the lower wall. As each stitch was tied, the skin was deeply inverted. This mode of suturing secures healing by granulation from the very bottom of the wound, but as this arrangement makes the wound unnecessarily wide, two or three tension sutures with Lister's lead plates were introduced. These greatly diminished the width of the wound. The usual antiseptic dressing and a spica bandage completed the operation.

MEDICAL PROGRESS.

Salolized Collodion for Rheumatic Joints.—The following prescription, to be used as an external application in acute rheumatism, is quoted by the *London Medical Recorder*:

R.—Salol, Ether, } of each . . . 4 parts.
Collodion . . . . 30 " —M.

Test for Exalgin.—According to the *American Journal of Pharmacy*, exalgin may be distinguished from acetanilid and phenacetin by the following simple test: 1 grain is dissolved in 2 cc. of chloroform and 20 cc. of petroleum ether added. If the exalgin is unadulterated the solution will remain clear. Moreover, phenacetin requires 20 cc. of chloroform and acetanilid 6 cc. for solution.

Prescription for Rickets.—Kassowitz prescribes the following mixture to children suffering from rhachitis:

R.—Phosphorus . . . . ⅙ grain.
Lipanin . . . . 7½ drachms.
White sugar, Acacia, } of each . 3½ "
Distilled water . . . 1¼ ounces.—M.

One teaspoonful three times daily.—*Der Kinder-Artz*, January, 1890.

Herpes Menstrualis.—Contrary to many writers, Bergh (*Monatshefte f. praktische Dermatologie*) believes herpes genitalis to be as frequent in woman as in man, his opinion being based upon the observation of 877 prostitutes in Copenhagen. Among these patients he noted 644 cases of herpes occurring about the menstrual period. With some women herpes was an invariable accompaniment of menstruation; with others it only occasionally appeared. The cause, he believes, is a disturbance of in-

nervation. The most usual seat was on the labia majora and adjacent parts; in five the uterus was involved. In a few the eruption appeared not only on the genitals, but on the face. The author does not believe that herpes appears only in those who have suffered from venereal diseases, as he has seen it in women without a venereal history.—*Centralblatt für die medicinischen Wissenschaften*, February 22, 1890.

Treatment of Post-partum Hæmorrhage.—DR. DIRSKA, in the *Berliner klinische Wochenschrift*, February 24, 1890, describes a method of treating post-partum hæmorrhage which he has practised successfully on more than thirty cases, excluding patients who, when first seen, were *in articulo mortis*. After the uterus is thoroughly emptied, it is grasped through the abdomen, and with the other hand two or three pieces of clean and transparent ice the size of a walnut are carried into the uterus and upper part of the vagina, where they are allowed to remain a few minutes. The external compression of the uterus is continued for fifteen minutes. According to the author, the bleeding stops immediately and permanently. The previous complete emptying of the uterus he considers of great importance, as clots will prevent thorough contraction.

Dirska has never seen bad symptoms follow this treatment, but he insists on the importance of using as pure and germ-free ice as is obtainable; moreover, he suggests that in hospitals ice might be artificially made for the purpose from sterilized water. After using ordinary ice the risks of septic infection can be reduced by intra-uterine injections of an ice-cold antiseptic solution. Cold fluids, however, cannot be used in place of the ice, as the latter acts not only through its temperature, but by virtue of the fact that it is a foreign body.
